## Declaration

I herewith give assurance that I completed this dissertation independently without prohibited assistance of third parties or aids other than those identified in this dissertation. All passages that are drawn from published or unpublished writings, either word-for-word or in paraphrase, have been clearly identified as such. Third parties were not involved in the drafting of the content of this dissertation; most specifically, I did not employ the assistance of a dissertation advisor. This work has not yet been submitted to another examination institution, neither in the same nor in a similar way and has not yet been published.

## Abstract

The continuous blurring of corporate boundaries induced by the development of globally networked supply chains and the associated interconnection of IT infrastructures is increasing the potential attack surface and velocity of cyber attacks, which requires the development of innovative defense solutions. Collaborative Intrusion Detection Systems (CIDSs) attempt to improve attack detection with intelligent mechanisms for information sharing and correlation. All approaches that implement techniques for data dissemination in CIDS face the same key challenges. To begin, privacy must be ensured when exchanging sensitive data, while on the other hand the usability of the data for subsequent applications, such as Machine Learning (ML)-based classification, must not be compromised. Similarly, the information exchange itself is subject to a trade-off between rapid dissemination among members, i.e. minimal overhead, and the quality of the data. Finally, interoperability must be ensured so that collaboration between different local IDSs is enabled in the first place. In this context, a novel CIDS that exchanges the parameters of generative machine learning models, is presented. Specifically, data sets are partitioned using locality-sensitive hashing (LSH) and persisted locally in a key-value store by using a corresponding hash value as a component for the key creation. This way, updates on specific regions are propagated automatically downstream through the processing pipeline, where regions are classified on a global level as either complex or simple with respect to the number of classes they contain. Complex regions are subject to the generative model selection process. The respective data partition in a region serves as input for the training of a Gaussian Mixture Model (GMM), whose parameters in turn is shared among members of the CIDS. An event-based streaming application implements the proposed approach and guarantees a fast distribution of information. By compressing local data into generative models, the exchanged data volume is reduced, likewise supporting data privacy. Processing latency is shortened by exploiting parallelization induced by the data partitioning. By exchanging only hashed values, model parameters and class labels, data privacy is preserved. Multiclass classification experiments on multiple network intrusion datasets demonstrate a superior performance of this approach in comparison to local detection schemes.

# Chapter 1

## Introduction

## 1.1 Problem Description

Many facets of modern society are based on information technology infrastructures, which exhibit an increasing degree of complexity and interconnection. Companies and institutions use IT systems to provide their services, enabling processes to be managed and handled both more effectively and more efficiently. As a consequence of this shift of processes onto IT systems, our society is becoming increasingly dependent on these systems. From these developments it can be derived that the protection of IT systems against malfunctions and espionage is of high importance. Thus, Intrusion Detection Systems (IDSs) are a key asset in IT infrastructures to secure individual computer systems or networks. When securing computer networks, some form of IP packet analysis is often used to monitor network traffic based on packet header or payload data. However, Deep Packet Inspection (DPI) is very resource-intensive, making it difficult to monitor high-volume networks, especially those characterized by high dynamics where a forecast of the required resources is practically impossible [Dre+04]. Another drawback of DPI solutions is that traffic from applications that encrypt their traffic end-to-end cannot be analyzed. A more scalable approach for network-based monitoring is to analyze network flows using flow exporters that collect and summarize packet header data and provide it as features for classification, for instance [Hof+18]. The topic of flow feature classification using ML algorithms in the context of intrusion detection is popular in the research community [Ahm+21]. However, the adoption rate of flow monitoring for detecting attacks on IT infrastructures is relatively low in practice due to fundamental challenges that ML-based detection of attacks poses [SP10]. First, the costs incurred by errors in the model, especially false positives, are relatively high in this context. Furthermore, the results of many ML algorithms are difficult to interpret, whereupon the transparency of detection suffers. Finally, collecting high quality data for training the models is a major challenge. Regardless of the question whether the fundamental challenges of IDSs based on flow data and machine learning can be solved sufficiently in the future, this work proceeds in that context and employs it as a use case for addressing challenges of another topic. In particular, when considering the development of the current threat environment, the effectiveness of conventional IDSs is limited. Technology trends, such as the internet of things or cloud computing, are main drivers for increasingly blurring corporate boundaries in the context of interconnection of infrastructures and shared resources. This transformation increases the potential attack surface of productive computer systems for large-scale and high-velocity cyber attacks, which traditional IDSs have limited effectiveness due to their isolated nature. Due to the mentioned increase of attack surface that is related to the size of current computer networks, attackers may attempt to obfuscate the characteristics of an intrusion by spreading single attack steps among multiple systems or networks. A common scenario would be scanning networks for opportunities to launch an intrusion, for example by executing port scans. By slowing down the velocity of such techniques, attackers are able to evade current firewalls and IDSs [RGH12]. Furthermore, it is common practice for attackers to perform automated attacks on a large number of different targets in order to speed up the identification of security vulnerabilities [Sav05]. For this reason, it is reasonable to assume that identical or similar stealthy scans are performed on multiple infrastructures simultaneously. Isolated IDS will not be able to create connections between such security events that occur at different infrastructures. In order to address the aforementioned

security problems, CIDS have been proposed. A CIDS refers to a network of multiple IDSs that exchange data with each other in order to increase detection performance, especially for distributed and novel attacks. In addition to an improved attack detection, another advantage is that CIDS scale better than isolated IDSs, making them more suitable for monitoring large-scale networks. By sharing resources across different infrastructures, peak loads can be served using a loadbalancing strategy. Current literature divides the main functions of an IDS into different components [Vas16]. Among these different components, the data dissemination is responsible for efficiently distributing the data that is collected and aggregated by the different IDSs in the network and thus avoiding unnecessary overhead in the CIDS. In addition to the advantages a CIDS provides, other challenges are introduced that need to be considered. In particular, the data dissemination is confronted with the following challenges. As already mentioned, the communication overhead is a central aspect that determines the efficiency of the CIDS and thus the latency of information distribution among individual members. Furthermore, data privacy plays an important role, since sensitive data containing security-relevant information may not be shared without further ado. However, in order to enable the distribution of information, different techniques, for instance Bloom Filters [Vas+15] [Loc+05], are employed. Finally, the dissemination must be performed in such a way that different IDSs can communicate with each other. Thus, a greater degree of interoperability requires fewer constraints and commitments on the part of local IDS.

## 1.2 Contribution

Current CIDSs address the challenges related to data dissemination only in one particular niche aspect, as existing approaches generally focus on the distribution of simple alarm data. A communication beyond this, for example the exchange of specific attack patterns that could fill knowledge gaps in the context of ML-based attack detection, is not feasible with the respective approaches. While ML-based attack detection offers many opportunities by providing powerful tools for identifying complex attack sequences, it still faces significant challenges, especially in the context of training data. For example, existing training data quickly becomes outdated and collecting new data is a complex task. Thus, as new malware and attack patterns emerge dynamically, effective mechanisms for sharing attack information must be found, such that different infrastructures can support each other and manage that process collectively.

Hence, this work aims to enable the dissemination of training data among the members of a CIDS while meeting the requirements imposed by the challenges in the context of data dissemination. For that, an innovative CIDS architecture is developed and assessed in a novel evaluation procedure. Specifically, an efficient and privacy-friendly storage and dissemination solution called *Pattern Database* is introduced. Attack data intended to be shared is used to train generative ML models. Subsequently, the respective model parameters are disseminated in the CIDS, such that attack information can be extracted in local infrastructures by creating synthetic data. By simulating knowledge gaps within local infrastructures, the Pattern Database is tested for its ability to fill the missing attack information using the synthetic data. In addition to that, a two-step detection process that employs the Pattern Database for classification is presented and evaluated for its detection performance.

This work is relevant to readers interested in intrusion detection, especially collaborative intrusion detection. However, anyone experiencing a similar use case, i.e., the efficient and anonymous sharing of structured data for subsequent use in ML algorithms, will also benefit from this work. The following Research Questions (RQs) summarise the objectives and contributions of this work mentioned so far and add additional aspects to complement the research.

- RQ 1: Can subsets of datasets from different infrastructures replace each other and provide equivalent information for a subsequent fitting of ML models so that the same detection performance is achieved as with the original data?
- RQ 2: How can a data dissemination component of a CIDS be designed in order to meet the key requirements, namely minimal overhead, data privacy and interoperability.
- RQ 3: How does this approach address the typical trade-off between anonymity of data and usability of data in the context of privacy-aware data exchange?
- RQ 4: How can the effect of a CIDS on the detection performance of individual IDSs be measured on a general level.

## 1.3 Methodology

In order to answer the above stated questions, a prototype application will be developed that realizes all concepts that aim to achieve the specified objectives. For this purpose, a detailed specification of the architecture and algorithms is provided first. For this purpose, a detailed specification of the architecture and algorithms is provided first. Subsequently, the application is evaluated by comprehensive experiments. The effectiveness of the data after inserting it into and retrieving it from the the Pattern Database for classification will be investigated and directly compared with the effectiveness of the original data that has not been subjected to any transformations. Furthermore, the compression properties of the system with respect to data persistence will be analyzed.

To be specific, network packet data from corresponding intrusion detection datasets for the evaluation of IDS are used to create datasets. For this purpose, three different datasets are selected, each of which is representative for the network traffic of a single infrastructure. A flow exporter is used to extract network flows from the packet data, which are then subject to further preprocessing steps, such as cleaning and labeling, using the information provided with the datasets. Basically, the data are network packets that are generated and captured in test environments. Among them are benign traffic traces representing the usual behavior of users in productive computer networks and attack data traces that are created with commonly used tools for intruding into computer networks. The datasets have both differences and similarities regarding the contained attack classes, such that the basis for evaluating the exchange of attack information is balanced and results in a realistic collaboration scenario. The effectiveness of data dissemination is determined by the change in classification performance, measured by various metrics, that results from participation in the CIDS. Finally, while the aspects of data privacy and interoperability are explained by the description of the architecture, the aspect of minimal overhead is investigated by analysing the exchanged data volume.

## 1.4 Thesis Outline

The thesis consists of a total of 6 chapters and is mainly organized into a theoretical part (Chapter 2 and 3) and a practical part (Chapter 4 and 5). The theoretical part exclusively covers contents that can be sourced in the literature. In contrast, the practical part develops original contents, some of which are based on knowledge and concepts acquired in the theoretical part. A detailed overview of the thesis structure is given in the following.

**Chapter 2** First, the preliminaries chapter provides the reader with basic background information regarding the topics of Intrusion Detection, Locality Sensitive Hashing, Gaussian Mixtures and Principal Component Analysis. While the topic Intrusion Detection gives a general overview of the context of this work, the remaining topics are more specific and provide a detailed insight into techniques and algorithms that are used to realize the proposed CIDS architecture.

**Chapter 3** In this chapter, the current state of the art in three different areas related to this thesis is summarized and briefly discussed. First, techniques for data dissemination in CIDSs are examined and the main challenges in this context are highlighted. Then, various established and novel approaches that use some form of similarity hashing in the context of intrusion detection are presented. Finally, the advantages of generative algorithms for intrusion detection are analyzed.

**Chapter 4** Based on the main challenges for data dissemination, this chapter develops a CIDS architecture that realizes the principles of Generative Pattern Dissemination, introducing a novel approach in the field of intrusion detection. After a general introduction of the idea and functionality, a detailed specification of the architecture and the developed algorithms is given.

**Chapter 5** Furthermore, the proposed architecture is evaluated by conducting comprehensive experiments that simulate different scenarios. The evaluation focuses on two key features of the CIDS. First, it is examined whether participating in the CIDS improves the detection in each of the individual member infrastructures when local knowledge gaps exist. Then, the communication overhead of the architecture is analyzed. Both aspects are compared to a baseline scenario.

**Chapter 6** This chapter concludes the thesis by discussing the stated research questions and summarizing the contributions. Finally, several aspects from the evaluation will be addressed to discuss possible improvements to the architecture and to identify potential future work.

# Chapter 2

## Preliminaries

## 2.1 Intrusion Detection

This section introduces the topic of intrusion detection and some important subcategories in the context of the thesis. First, IDSs are described and categorized according to different characteristics. The advantages and disadvantages of individual types of IDS are explained and examples are referred to individually. The topic of network flow monitoring is then addressed, since it is an essential component of network monitoring that is incorporated in the proposed architecture. The role of network flows in the context of network monitoring and management is motivated and the typical processes of a flow exporter are described. In the context of the shortcomings of conventional IDSs for protecting large scale systems against coordinated and distributed attacks CIDSs are introduced. For this purpose, it is first described what coordinated and distributed attacks are. Then it is explained what constitutes a CIDS, what requirements exist for the realization of CIDS, and what components and processes CIDS typically consist of.

### 2.1.1 Intrusion Detection Systems

Classic security mechanisms, such as encryption or firewalls, are considered as preventive measures for protecting IT infrastructures. However, in order to be able to react to security breaches that have already occurred, additional reactive mechanisms are required. To complement preventive measures, IDSs have been commercially available since the late 1990s [WM18, p. 27]. Generally, the main reason for operating an IDS is to monitor and analyze computer networks or systems in order to identify anomalies, intrusions or privacy violations [Hin+20]. Specifically, the following three significant advantages are pointed out [WM18, p. 391].

- IDSs can detect the preliminaries of attacks, in particular the organized gathering of information about networks and defense mechanisms (attack reconnaissance), and thus enable the prevention or mitigation of damage to information assets.
- IDSs can help protect information assets when known vulnerabilities cannot be fixed fast enough, notably in the context of an rapidly changing threat environment.
- The occurrence of unknown security vulnerabilities (zero day vulnerabilities) is not predictable, meaning that no specific preparations can be made for them. However, IDSs can identify processes in the IT system that deviate from the normal state and thus contribute to the detection of zero day attacks.

For an effective IDS, it is important to be able to detect as many steps as possible within the prototypical attack sequence, also called kill chain [WM18, p. 393]. Since a successful intrusion into a system can be stopped at several points in this sequence, the effectiveness of the IDS increases with its functionality. The following categorization (see Figure 2.1) of intrusion attempts according to [Ken99] reflects parts of that chain.

Probing refers to the preambles of actual attacks, also known as attack reconnaissance. This includes obtaining information about an organization and its network behavior (footprinting) and obtaining detailed information about the used operating systems, network protocols or hardware devices (fingerprinting).

Figure 2.1: A categorization of intrusions into different subtypes

Denial of Service (DoS) refers to an attack aimed at disabling a particular service for legitimate users by overloading the target systems processing capacity. Remote to Local (R2L) attacks attempt to gain local access to the target system via a network connection. And one step further, User to Root (U2R) attacks start out with user access on the system and gain root access by exploiting vulnerabilities. Individual intrusion types can but do not have to be executed consecutively. For example, it is not mandatory to render a system incapable of action by DoS in order to subsequently gain local access to the target. However, this may be part of a strategy.

Additionally, IDSs are generally categorized by the detection scope and the employed attack detection method [Mil+15]. Hence, a distinction is made between Host-based Intrusion Detection Systems (HIDSs) and Network-based Intrusion Detection Systems (NIDSs). While a HIDS resides on a system, known as host, only monitoring local activities, a NIDS resides on a network segment and monitors remote attacks that are carried out across the segment. In general, HIDS are advantageous if individual hosts are to be monitored. NIDS, on the other hand, are able to monitor traffic coming in and out of several hosts simultaneously. The disadvantage of NIDS, however, is that attacks can only be detected if they are also reflected in the network traffic. Pioneering examples in the context of HIDS are the Intrusion-Detection Expert System (IDES) [LTG92] and the Multics Intrusion Detection and Alerting System (MIDAS) [Seb+88]. A prominent representative in the area of NIDS is NetSTAT [VK98] [VK99].

Furthermore, IDSs are categorized into misuse-based detection and anomaly-based detection (see Figure 2.2). A misuse-based approach defines a model that describes intrusive behaviour and compares the system or network state against that model. An anomaly-based IDS, on the other hand, creates a statistical baseline profile of the system's or network's normal state and compares it with monitored activities. The concept of the NIDS origins from [Den87].

Figure 2.2: A taxonomy for IDS that distinguishes systems based on the utilized detection method or the scope in which it operates

Obviously, these two opposing approaches offer different advantages and disadvantages and are capable of complementing each other. Misuse-based systems can detect malicious behavior with a low false positive rate, but assume that the exact patterns are known. Typically, this method cannot detect novel [WM18, p. 403], metamorphic or polymorphic attacks [Szo05, p. 236]. An anomaly-based approach allows both known and unknown attacks to be detected, but the frequent occurrence of false-positive estimations is a major challenge. Given the amount of data that occurs in computer systems and networks nowadays, the generation of false alarms for even a fraction of this amount can render the IDS operationally unusable, since no network administrator can investigate such a large number of incidents in detail [Axe00]. Most implementations of misuse-based systems rely on the creation of signatures. A signature is similar to a collection of rules that describes an attack pattern. The most prominent signature-based IDS is Snort [Roe+99]. The payload-based anomaly detector PAYL [WS04] is an example for an anomaly-based system. Hybrid approaches are conceivable in order to circumvent the respective disadvantages of different subcategories of IDSs. The interested reader is referred to the following works [Dep+05] [ZZ06] [Bee21].

### 2.1.2 Network Flow Monitoring

Network monitoring is a key component for network management as network administrators derive decisions based on data that results from monitoring activities. By collecting data from network devices, such as switches, routers or clients, the current behaviour of the network is measured. Commonly, this behaviour has to meet some minimum application requirements, which can be summarized by the term Quality of Service (QoS) [TFW21, p. 406]. In this context, the most early and vague definition of a network flow was introduced as a sequence of packets traveling from the source to the destination [Cla88]. Here, no further characteristics of a flow are given and it is not clear how one flow is differentiated from another flow. Later in the 1990s, however, the demand arose for a finer-grained view of network traffic than that provided by interface-level counters, but without the disadvantage of the huge amounts of data generated by packet tracking. Evidently, the concept of network flows has filled this gap in demand and has gained a central role in network management and research today [TB11].

Since the first attempts at standardization in the 1990s through the efforts of the Internet Engineering Task Force (IETF), a number of proprietary standards have emerged as each network device vendor has implemented its own flow export protocol. In order to improve interoperability in the area of network flow measurement, the IETF, established the IP Flow Information Export (IPFIX) working group. This working group defined the IPFIX standard (RFC 5101), which defines the term network flow as follows.

**Definition 1** (Network Flow). A network flow is an aggregation of all network packets that pass an observation point of a network during a certain time interval and share a set of common properties. These properties are defined as the result of applying a function to the value of

1. one or more packet, transport or application header fields,
2. one or more characteristics of the packet itself,
3. one or more fields derived from packet treatment.

Figure 2.3: General Flow Monitoring Architecture

This definition is loose enough to cover the range from a flow containing all packets observed at a network interface to a flow that consists only of a single packet between two applications. Note, that this definition of the set of properties is also less strict than the conventional definition of the five-tuple consisting of source IP address, source port, destination IP address, destination port and protocol [Cla08].

In general, network flows can appear either as unidirectional flow, which aggregates all packets from one host to another host, or as bidirectional format, that aggregates all packets regardless of direction. Depending on which flow format and flow exporter is used, additional information, e.g. statistical calculations on bytes per second, can be obtained. Other common network flow protocols are NetFlow [Cla04], OpenFlow [McK+08] and sFlow [Pha].

Systems that generate flow data and extract additional information are called flow exporters. Generally, flow exporters are part of a general flow monitoring architecture [Hof+14], that consists of four different processes (see Figure 2.3). The packet observation is done on interfaces of packet forwarding devices by capturing network packets and executing specific preprocessing steps like timestamping and truncation. The process of flow metering describes the aggregation of packets into flow records. There, a set of functions, including packet header capturing, timestamping, sampling and classifying is applied on values of the packet stream listed above. Furthermore, flow records are maintained, which may include creating, deleting or updating records, or computing statistical flow features. After that, the exporting process places flow records in a datagram of the deployed export protocol and sends them to one or more collecting processes. Finally, the collection process is responsible for the reception, storage and preprocessing of flow records, produced by the preceding step. Typically, the collected data is analyzed. This can be done, for example, in the context of an IDS.

Using network flows for intrusion detection has several advantages over DPI. For example, DPI requires highly complex and expensive infrastructure for storage and analysis of the data [Hof+14]. Since flow exporter setups rely on packet header fields and statistical aggregations, a significant data reduction is achieved, which is why an analysis of network flows is scalable and also applicable for high-speed networks [Hof+14]. In addition, discarding the payload results in a better compliance with data retention laws and privacy policies.

### 2.1.3 Collaborative Intrusion Detection

With the commercialization of cloud products, various aspects related to the security of computer networks have also become more stringent. Not only has part of the responsibility for securing servers and networks shifted from the end customer to the service provider. The fact that computing resources within large data centers that are operated by public cloud providers are publicly accessible offers, on the one hand, a large contiguous attack surface. And on the other hand, a large amount of potential resources for executing so-called large-scale coordinated attacks are accessible to attackers.

Typically, large-scale coordinated attacks target a large number of hosts which are spread over a wide geographical area [ZLK10]. There, attackers make use of automation and sophisticated tools to target all vulnerable services at once instead of manually targeting services [Sav05]. In the context of cloud environments, attackers can hijack mismanaged user accounts and hack into poorly secured cloud deployments [KG19]. In this way, attackers can gain access to a variety of different resources to spread attacks across as many sources as possible, thus avoiding detection by security systems.

According to [ZLK10], large-scale coordinated attacks are difficult to detect by isolated IDS, because of their limited monitoring scope. For instance, in [RGH12] the authors show that a distributed portscan can be executed with relatively few resources without being detected when deploying Snort IDS and a commercial firewall solution. The experimental results show that the detection by the IDS can be bypassed most effectively by distributing the sources of a scan, whereas the detection by the firewall can be evaded by slowing down single executions of scans.

In order to detect large-scale coordinated attacks, evidence of intrusions from multiple different sources need to be combined. This idea leads to the development of CIDS, where the aggregation and correlation of data originating from different IDSs creates a holistic picture of the network to be monitored and enables the detection of distributed and coordinated attacks [Vas16, p. 24]. CIDS are also a solution to zero day attacks, because information about novel attacks can be shared with participants of the CIDS in order to mitigate such attacks at an early stage. In addition to the aspect of improved detection, another advantage is the improved scaling for the protection of large IT systems. CIDSs can monitor large-scale networks more effectively with the realization of a loadbalancing strategy. By sharing IDS resources across different infrastructures peak loads can be served resulting in a reduced downtime of individual IDSs.

In general, a CIDS is defined as a network of several intrusion detection components that collect and exchange data on system security. The tasks of a CIDS can be allocated across two main components, namely the monitoring units and the analysis units. Monitoring units can be considered as conventional IDS that monitor a sub-network or a host and by that, generate low-level intrusion alerts. Analysis units are responsible for merging the low-level intrusion alerts and their further post-processing. This includes, for instance, the correlation of the alerts, the generation of reports or the distribution of the information to the participants of the network. The communication between the monitoring and analysis units is largely determined by the architecture of the CIDS.

CIDS architectures can be categorized into centralized, hierarchical and decentralized approaches [ZLK10] (see Figure 2.4). Centralized architectures [CM02][MI03], consisting of multiple monitoring units and a central analysis unit, suffer from a conceptual single point of failure (SPoF) and are limited in their scalability due to a bottleneck, which is introduced by the central analysis unit. However, in practice the SPoF can be avoided if individual components are implemented redundantly and form a centralized architecture only at the logical level. A bottleneck, on the other hand, is usually avoided by a distributed implementation of the logically centralized architecture. Hierarchical designs exhibit multiple monitoring and analysis units organized in a tree-based topology [PN97] [Zha+01] [Ngu+19]. These systems are restricted in their scalability by the respective instances on higher levels, whose failure results in a malfunction of the respective sub-trees [ZLK10].

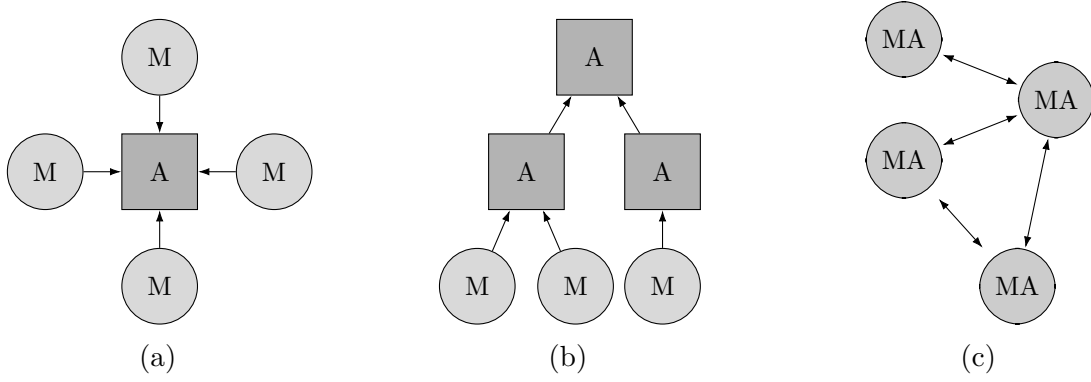

Figure 2.4: CIDS architectures: (a) centralized, (b) hierarchical or (c) distributed layout of monitoring (M) and aggregation units (A)

Again, such disadvantages only play a major role in non-redundantly implemented systems. Additionally, there exist approaches that are inherently distributed. Distributed architectures [JWQ03] [Fun+08] [Vas+15], wherein each participating system consists of both a monitoring and analysis unit and where the communication is based on some form of data distribution protocol, are considered as scalable by design. However, they depend on effective and consistent data dissemination and the data attribute selected for correlation may affect load distribution among participants [ZLK10].

The authors in [Vas+15] describe the most important requirements that a CIDS has to meet. Additionally, they further categorize the components of a CIDS by function. The following is a summary of these requirements and components. Six requirements are defined, namely accuracy, minimal overhead and scalability, resilience, privacy, self-configuration and lastly interoperability. In this context, accuracy generally describes a collection of evaluation metrics for assessing the performance of the CIDS. Frequently used metrics are, for example, the Detection Rate (DR), i.e. the ratio of correctly detected attacks to the total number of attacks, or the False Positive Rate (FPR), which sets the number of normal data classified as an attack in relation to the total number of normal data. Obviously, a CIDS is expected to have higher accuracy in terms of attack detection than isolated IDSs. The requirement for minimal overhead and scalability addresses the operational overhead and the scalability of the system. First, the algorithms and techniques for collecting, correlating, and aggregating data must require minimal computational overhead. Second, data distribution within the CIDS must be efficient. The performance required to operate the system should increase linearly with the resources used, so that computer systems of any size can be protected by the CIDS. This property can be measured in theoretical terms by considering the complexity of the algorithms used. In practical terms, the passed time from the collection of a data point to the decision-making process can be measured. Resilience describes the ability of the system to be resistant to attacks, manipulations and system failures. A distinction is made between external attacks, such as DoS, and internal attacks by infiltrated CIDS components. Moreover, it also covers fail-safety in general, which can be achieved, for example, by avoiding SPoFs.

With regard to the protection and regulation of privacy in the CIDS, a distinction is made between internal and external communication. Data that is exchanged internally in the CIDS network between members may contain potentially sensitive information.

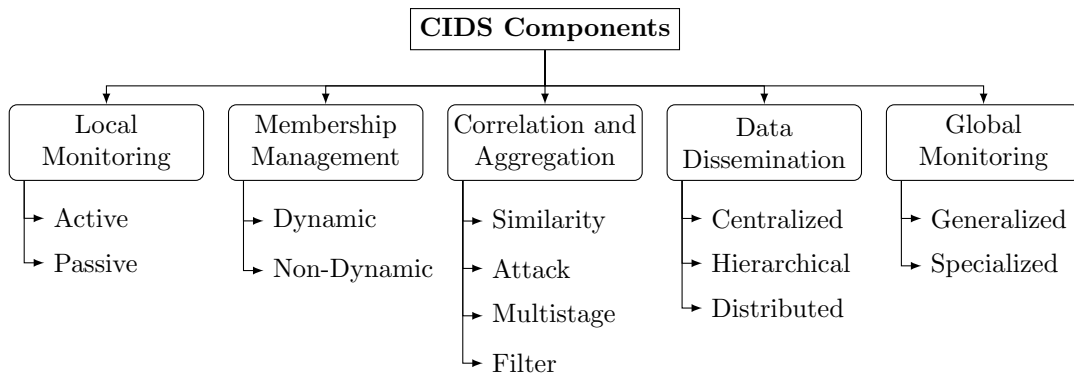

Figure 2.5: Components of CIDS according to functions

Such information should not be disclosed directly to other participants for reasons of data privacy. This includes, among other things, legal aspects when it comes to sharing log and network data. In connection with the resilience of the system, securing communication against third parties using cryptographic methods also plays a role and represents a major challenge, especially in dynamically distributed architectures. Self-configuration describes the degree of automation of a system with regard to configuration and operation. Particularly in distributed and complex architectures, a high degree of automation is desired in order to avoid operating errors and enable automatic resolution of component failures. Finally, individual components of the overall system, which were deployed in different system and network environments, should be able to interact with each other in the context of the CIDS. In addition to system-wide standards for data collection, processing and exchange, there exists a trade-off between interoperability and privacy.

The domains into which the components of the CIDS can be grouped are referred to as local monitoring, membership management, correlation and aggregation, data dissemination, and global monitoring. In the context of local monitoring, a distinction is made between active and passive monitoring. Active monitoring refers to the use of honeypots that reveal themselves as attack targets in the infrastructure in order to collect attack data. Passive monitoring involves intrusion detection activity at the host or network level, which in turn can be divided into misuse-based or anomaly-based methods according to the type of detection technique used (see Section 2.1.1).

Membership management refers to ensuring secure communication channels in the form of an overlay network. Generally, membership management is categorized according to the organization and structure of the system topology. In terms of organization, there are either static approaches, in which members are added or removed manually, or dynamic approaches, in which components are organized automatically via a central entity or a protocol. Furthermore, the structure of the overlay network is relevant for the type of communication in the CIDS network. This means that connections between the monitoring and analysis units are either centralized, hierarchical or distributed.

Before collected and analyzed data are shared with other participants in the CIDS network, the data is correlated and similar data points are aggregated. The main purpose of generating global and synthetic alerts is firstly to reduce the amount of alerts overall and secondly to improve data insights. Correlation mechanisms can be categorized into single-monitor and monitor-to-monitor approaches.

Single-monitor methods correlate data locally without sharing data with other monitor entities. Monitor-to-monitor approaches, on the other hand, share data with other monitoring units in order to correlate local data with shared data and thus enable insights that go beyond isolated methods. Further, a classification can be made according to the correlation techniques used, grouping four different approaches.

Similarity-based approaches correlate data based on the similarity of one or more attributes. For instance, [DW01] suggests using the 5-tuple information of the network data to detect duplicates within NIDSs. The computation of similarity can be done in a variety of ways. For example, [VS01] defines a similarity function for each attribute and computes the overall data similarity by combining the functions using an expectation of similarity. High-dimensional data is usually problematic, as the difficulty for an effective calculation of similarity increases with the number of attributes [ZLK09].

Attack scenario-based approaches detect complex attacks based on databases that provide patterns for attack scenarios [Gar+04] [DC02]. Such approaches have high accuracy for already known attacks. However, the accuracy decreases as soon as the patterns in the real data deviate from those in the database, since the definition of the scenario-rules are of a static quality in these approaches.

Multistage alert correlation aims to detect unknown multistage attacks by correlating defined pre- and post-conditions of individual alerts [CM02] [CLF03]. The idea behind the approach is based on the assumption that an attack is executed in preparation for a next step. The system states before and after an alert are modeled as pre- and postconditions, which are correlated with each other. While these approaches are more flexible than the all-static definition of attack scenarios, they still require the prior modeling of pre- and postconditions, which are based on expert knowledge.

Filter-based approaches filter irrelevant data in order to reduce the number of alerts within the intrusion detection context. For example, [PFV02] filters alerts by a ranking based on priorities of incidents. Priorities are calculated through comparing the target's known topology with the vulnerability requirements of the incident type. The rank that each alert is assigned to provides the probability for its validity. The accuracy of the filters is based on the quality of the description of the topology to be protected and require reconfiguration when changes are made to the infrastructure.

Data Dissemination describes the efficient distribution of correlated and aggregated data in the CIDS network. How the data is disseminated is strongly influenced by the topology and membership management of the system. Centralized topologies have a predefined flow of information from the monitoring units to the central analysis unit. If the system is organized hierarchically, information flows statically or dynamically organized from lower monitoring units in the hierarchy to higher units. Distributed topologies allow the use of versatile strategies, such as flooding, selective flooding or publish-subscribe methods.

Global monitoring mechanisms are needed for the detection of distributed attacks which isolated IDSs cannot detect due to the limited information base. Thus, the detection of distributed attacks relies on the insight obtained by combining data from different infrastructures. This means that global monitoring is strongly dependent on the employed correlation and aggregation techniques. The overall strategy of the CIDS is described by global monitoring and can have both generic and specific objectives.

## 2.2 Locality Sensitive Hashing

Finding similar objects, formally known as the nearest-neighbour search problem (NNP), is a central problem in computer science in general. And besides the exact search, it is also an important topic in the field of intrusion detection. For example, exact searches allow to compare the signatures of known malware with low false positive rates. Considering polymorphic attacks, however, it is essential to also detect all objects that are similar to the known attack and thus detect modified forms of it. In this context, this section presents a well-studied approach called LSH that solves an approximate version of the NNP by partitioning the search space with a hash function. This way, the searching problem is reduced to pairs that are most likely to be similar. Besides the application for solving the NNP, for which LSH was originally conceived, the concept has been proven to be effective for numerous other use cases, such as dimensionality reduction, clustering or classification. As the proposed generative pattern database integrates a locality-sensitive hash function for enabling both similarity search and data parallelism, LSH and a specific variant called gaussian random projection (GRP) is described in detail in this section.

Section 2.2.1 introduces the approximate version of the NNP as it is a prerequisite for the general definition of LSH. After that, Section 2.2.2 begins by clarifying the core idea of LSH and subsequently explains how to construct a locality-sensitive hash function. Lastly, GRP that uses the cosine distance for similarity calculations is presented in Section 2.2.3.

### 2.2.1 The Approximate Nearest Neighbour Problem

For general definitions of the NNP and its variants, a set of points  $\mathcal{P} = \{\mathbf{p}_1, \dots, \mathbf{p}_N\}$  in a metric space  $(\mathcal{X}, d)$  with  $\mathcal{P} \subset \mathcal{X}$  and where  $d$  is a metric on  $\mathcal{X}$ , i.e., a function  $d : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$  is considered. It is assumed that  $d$  is a proper metric, which means that it is

1. *symmetric*:  $d(\mathbf{p}, \mathbf{q}) = d(\mathbf{q}, \mathbf{p})$ ,
2. *reflexive*:  $d(\mathbf{p}, \mathbf{q}) \leq 0$ ,  $d(\mathbf{p}, \mathbf{q}) = 0 \iff \mathbf{p} = \mathbf{q}$  and satisfies the
3. *triangle inequality*:  $d(\mathbf{p}, \mathbf{q}) \leq d(\mathbf{p}, \mathbf{s}) + d(\mathbf{s}, \mathbf{q})$ .

Given these assumptions, the authors in [IM98] define the NNP as stated in Definition 2. As the algorithms in the presented approach operate on vectors of statistical flow features (see Section 2.1.2), the input set is restricted to  $\mathbb{R}^D$ . In particular, the input data is considered to be high dimensional, such that  $D \gg 1$ , and could define  $d$  as, e.g., the euclidean distance. In this case, an exhaustive search would require a query time of  $O(D \cdot N)$ . Unfortunately, all exact algorithms that provide a better time complexity than an exhaustive search require  $O(2^D)$  space [Rub18].

**Definition 2** (Nearest-neighbour search problem[IM98]). Construct a data structure so as to efficiently answer the following query: Given any query point  $\mathbf{q} \in \mathcal{X}$ , find some point  $\mathbf{p} \in \mathcal{P}$  such that

$$\min_{\mathbf{p} \in \mathcal{P}} d(\mathbf{p}, \mathbf{q}). \quad (2.1)$$

Figure 2.6: In the  $cr$ -approximate nearest-neighbour problem some point within  $cr$  is accepted, if there exists a point  $p$  where  $d(p, q) \leq r$ .

This tradeoff between time and space complexity is usually referred to as “curse of dimensionality” and can only be resolved by accepting approximate solutions. In [IM98] the  $c$ -approximate nearest-neighbour problem ( $c$ -ANNP) is defined as follows.

**Definition 3** ( $c$ -Approximate nearest-neighbour search problem). For any given query point  $q \in \mathcal{X}$  and some approximation factor  $c > 1$ , find some point  $p \in \mathcal{P}$  such that

$$d(p, q) < c \cdot \min_{s \in \mathcal{P}} d(s, q). \quad (2.2)$$

Thus, the distance from the query point  $q$  to the approximate nearest neighbour  $p$  is at most  $c$  times the distance to the true nearest neighbour  $s$ . However, LSH does not solve the  $c$ -ANNP directly. Instead, the authors in [IM98] relax the problem by introducing the  $cr$ -approximate nearest-neighbour problem ( $cr$ -ANNP).

**Definition 4** ( $cr$ -Approximate nearest-neighbour search problem). For any given query point  $q \in \mathcal{X}$ , some approximation factor  $c > 1$  and some target distance  $r > 0$ , if there exists a point  $p \in \mathcal{P}$  where  $d(p, q) \leq r$ , then return a point  $p' \in \mathcal{P}$  where

$$d(p', q) \leq cr. \quad (2.3)$$

Figure 2.6 depicts the  $cr$ -ANNP. The distance  $r$  represents the distance of the query object from its nearest neighbour. If there is such a point, the algorithm returns points within  $cr$  distance from the query object, else it returns nothing. In [IM98] it is shown that LSH can solve the  $c$ -ANNP by solving the  $cr$ -ANNP for different settings of  $r$ .

## 2.2.2 Locality-Sensitive Hash Functions

Introduced by Indyk and Motwani in 1998 [IM98] as an algorithm that solves the  $c$ -ANNP, LSH has since been extensively researched and is now considered among the state of the art for approximate searches in high-dimensional spaces.<sup>1</sup> The basic idea of the approach is to partition the input data using a hash function that is sensitive to the location of the input within the metric space. This way, similar inputs collide with a higher probability than inputs that are far apart. Thus, LSH exhibits fundamental differences to conventional hash functions.<sup>2</sup>

A hash function is a function that maps a large input set to a smaller target set. The elements of the input set are called *messages* or *keys* and may be of arbitrary different lengths. The elements of the target set are called *digests* or *hash values* and are of fixed size length.

<sup>1</sup>See [NBJ21] for an exhaustive survey of techniques that solve the NNP.

<sup>2</sup>Cryptographic and non-cryptographic hash functions are referred to conventional hashing.

Figure 2.7: The behaviour of a conventional hashing function  $h$  and a locality-sensitive hashing function  $h_{\text{LSH}}$  when hashing very similar messages  $\mathbf{m} \approx \mathbf{m}$ , similar messages  $\mathbf{m} \sim \mathbf{m}$  and non-similar messages  $\mathbf{m} \not\sim \mathbf{m}$  into the slots of a hash table  $T_1$  and  $T_2$  respectively.

We define a conventional hash function as  $h : \mathcal{M} \rightarrow \mathcal{B}$  where  $\mathcal{M} \subset \mathcal{X}$  is the input set and  $\mathcal{B} = \{0, 1\}^K$  with  $K \in \mathbb{N}$  the target set of all bit sequences of fixed size  $K$ , with  $K < D$ . It follows that messages  $\mathbf{m} \in \mathcal{M}$  can only be mapped to  $2^K$  different binary strings  $\mathbf{b} \in \mathcal{B}$ . The probability that a given  $\mathbf{m}$  hashes to  $\mathbf{b} = h(\mathbf{m})$  is  $\frac{1}{2^K}$ . Typically, conventional hashing is used for the realization of, e.g., hash tables, data integrity checks, error correction methods or database indexes. Such applications require a randomly uniform distribution of messages on hashes. Thus, a conventional hash function should therefore ideally assign hash values uniformly distributed with probability  $\frac{1}{2^K}$  for all  $\mathbf{m}$  and all  $\mathbf{b}$ . A related property in this context is the probability of a *collision*. A collision occurs when two different messages  $\mathbf{m}_1 \neq \mathbf{m}_2$  are projected onto the same hash value  $h(\mathbf{m}_1) = h(\mathbf{m}_2)$ .

For example, cryptographic hash functions are used in systems, where additional security mechanisms are necessary. Thus, different security requirements are defined for cryptographic hash functions [Wil16, p. 349]. In particular, these hash functions are designed to be resistant against collisions. Applications that do not require the hash function to be resistant against adversaries, e.g., hash tables, caches or de-duplication, are usually implemented by using a non-cryptographic hash function that exhibits relaxed guarantees on the security properties in exchange for significant performance improvements. However, both cryptographic and non-cryptographic hash functions behave relatively similar with respect to the distribution of messages on hashes and the probability of a collision. In contrast, locality-sensitive hash functions behave more or less inversely as illustrated in Figure 2.7. A conventional hashing function  $h$  does not incorporate the similarity of messages into the calculation of the hash value. As a result, the messages are hashed evenly distributed into the slots of  $T_1$ . A locality-sensitive hashing function  $h_{\text{LSH}}$  on the other hand, hashes more similar messages into the same slot or neighbouring slots of  $T_2$  as the hashes reflect the similarity of the input messages. In this regard, a hash table is introduced as an array  $T$  in which each element is a subset of messages that share a common hash value. Additionally, the position, i.e., slot of each subset in  $T$  is determined by that common hash value. For simplicity, we refer to a less mathematically sound notation within an algorithm description. Thus, the insert operation is denoted by  $T[\mathbf{b}] = \mathbf{m}$ , expressing that  $\mathbf{m}$  is stored at slot  $\mathbf{b} = h(\mathbf{m})$  within  $T$ . Conversely, the lookup operation is defined as  $\mathcal{M}_{\mathbf{b}} = T[\mathbf{b}]$  for retrieving the subset of messages associated with the key  $\mathbf{b}$ .

As a locality-sensitive hashing function can be constructed as a general concept, specific families of functions can be derived. We refer to a *family* of hash functions  $\mathcal{H} = \{h_1, \dots, h_K\}$ ,  $h_k : \mathcal{M} \rightarrow \mathcal{B}$  as a collection of hash functions that have the same domain and range, share a basic structure and are only differentiated by constants. Three basic requirements are demanded for such a family of functions [LRU14, p. 99].

1. Close pairs of input should be hashed into the same bucket with higher probability than distant pairs.
2. Functions within a family need to be statistically independent from one another, such that the FPR and FNR can be improved by combining two or more functions.
3. Functions need to be efficient, i.e., be faster compared to an exhaustive search.

The first step is to define LSH generally. Applied on the *cr*-ANN, the first requirement states, with high probability, two points  $\mathbf{p}, \mathbf{q}$  should hash to the same hash value if their distance is at most  $r$ , i.e.,  $d(\mathbf{p}, \mathbf{q}) \leq r$ . And if their distance is at least  $cr$ , the points should hash to different hash values, i.e.  $d(\mathbf{p}, \mathbf{q}) > cr$ . Thus, A formal definition of a locality-sensitive hash function is given as follows [AI06].

**Definition 5** (Locality-Sensitive Hash Function). Given a target distance  $r \in \mathbb{R}, r > 0$ , an approximation factor  $c \in \mathbb{R}, c > 1$  and probability thresholds  $p_1, p_2 \in \mathbb{R}$ , where  $p_1 > p_2$ , a family  $\mathcal{H} = \{h : \mathcal{P} \rightarrow \mathcal{B}\}$  is called  $(r, cr, p_1, p_2)$ -sensitive if for any two points  $\mathbf{p} \in \mathcal{P} \subset \mathcal{X}, \mathbf{q} \in \mathcal{X}$  and any hash function  $h$  chosen uniformly at random from  $\mathcal{H}$  the following conditions are satisfied:

$$\begin{aligned} d(\mathbf{p}, \mathbf{q}) \leq r &\implies P[h(\mathbf{p}) = h(\mathbf{q})] \geq p_1, \\ d(\mathbf{p}, \mathbf{q}) \geq cr &\implies P[h(\mathbf{p}) = h(\mathbf{q})] \leq p_2. \end{aligned}$$

Ideally, the gap between  $p_1$  and  $p_2$  should be as big as possible as depicted in Figure 2.8c, which in fact represents an exact search. This is, as already discussed, no option due to its time and space requirements. Considering a single locality-sensitive function as shown in Figure 2.8a, where the probability gap between  $p_1$  and  $p_2$  is relatively close, the false negative rate would be relatively high. Increasing the gap would require to increase  $c$  and lead to a high number of false positives. Therefore, a single function would provide only a tradeoff. But it is possible to increase  $p_1$  close to 1 and decrease  $p_2$  close to 0 while keeping  $r$  and  $cr$  fixed as shown in Figure 2.8b by introducing a process called *amplification*. By applying a logical AND-construction on  $\mathcal{H}$  both thresholds  $p_1$  and  $p_2$  are reduced. For that,  $K$  hash functions are sampled independently from  $\mathcal{H}$  and each point  $\mathbf{p}$  is hashed to a  $K$ -dimensional vector with a new constructed function  $g \in \mathcal{H}^K$  as

$$g(\mathbf{p}) = [h_1(\mathbf{p}), h_2(\mathbf{p}), \dots, h_K(\mathbf{p})]. \quad (2.4)$$

Since all hash functions  $\{h_1, \dots, h_K\} \in \mathcal{H}$  are statistically independent the product rule applies and for any two points  $\mathbf{p}$  and  $\mathbf{q}$ , a collision occurs if and only if  $h_k(\mathbf{p}) = h_k(\mathbf{q})$  for all  $k \in \{1, \dots, K\}$ . The probability gap is then defined as follows:

$$\begin{aligned} P[h_k(\mathbf{p}) = h_k(\mathbf{q})] \geq p_1 &\implies P[g(\mathbf{p}) = g(\mathbf{q})] \geq p_1^K \\ P[h_k(\mathbf{p}) = h_k(\mathbf{q})] \leq p_2 &\implies P[g(\mathbf{p}) = g(\mathbf{q})] \leq p_2^K. \end{aligned}$$

Figure 2.8: The behaviour of a  $(r, cr, p_1, p_2)$ -sensitive function in (a) and (b) (adapted from [LRU14, p. 100]) approaching the ideal probability gap in (c) resembling the behaviour of an exact search.

Thus, by increasing  $K$  the thresholds can be arbitrarily decreased. In order to increase both thresholds, the OR-construction is introduced. For that, a number of  $L \in \mathbb{N}$  functions  $g_1, \dots, g_L$  are constructed, where each function  $g_l$ ,  $l \in \{1, \dots, L\}$  stems from a different family  $\mathcal{H}_l$ . Note, that the algorithm is successful, when the two points  $\mathbf{p}, \mathbf{q}$  collide at least once for some  $g_l$ . For  $d(\mathbf{p}, \mathbf{q}) \leq r$ , the following probability for a collision is given by

$$\begin{aligned}
 P[\exists l \mid g_l(\mathbf{p}) = g_l(\mathbf{q})] &= 1 - P[\forall l \mid g_l(\mathbf{p}) \neq g_l(\mathbf{q})] \\
 &= 1 - P[g_l(\mathbf{p}) \neq g_l(\mathbf{q})]^L \\
 &\geq 1 - (1 - p_1^K)^L.
 \end{aligned}$$

As the AND-construction lowers both  $p_1$  and  $p_2$ , similarly the OR-construction rises both thresholds. By choosing  $K$  and  $L$  judiciously,  $p_2$  approaches zero while  $p_1$  approaches one. Both constructions may be concatenated in any order to manipulate  $p_1$  and  $p_2$ . Of course, the more constructions are used and the higher the values for the parameters  $K$  and  $L$  are picked, the more time is considered for the application of the function. The algorithm for solving the  $cr$ -ANNP using LSH consists of two consecutive steps, namely the preprocessing (Algorithm 1) and the query (Algorithm 2).

**Input:**  $N$  points  $\mathbf{p}_n \in \mathcal{P}$  with  $n \in \{1, \dots, N\}$ ,  $N \in \mathbb{N}$

**Output:** data structure  $\mathcal{T} = \{T_1, \dots, T_L\}$

- 1:  $\mathcal{T} \leftarrow \emptyset$
- 2: construct hash functions  $g_1, \dots, g_L$  each of length  $K$  (see Equation 2.4)
- 3: **for each**  $g_l \in \{g_1, \dots, g_L\}$  **do**
- 4:     $T_l \leftarrow$  new hash table
- 5:    **for each**  $\mathbf{p}_n \in \mathcal{P}$  **do**
- 6:      $T_l[g_l(\mathbf{p}_n)] \leftarrow \mathbf{p}_n$
- 7:    add  $T_l$  to  $\mathcal{T}$
- 8: **return**  $\mathcal{T}$

Algorithm 1: LSH Preprocessing

First, a set of points  $\mathcal{P}$  is required for the construction of the data structure  $\mathcal{T}$  as described in Algorithm 1. For each function  $g_l$  a corresponding hash table  $T_l$  is initialized that will store all data points  $\mathbf{p}_n$ . In other words, all data points are preprocessed and stored  $L$  times. The resulting data structure represents the database, which is searched through, when answering a query. Note, that a common collision handling method, such as separate chaining for example, is applied if a certain slot is already occupied.

**Input:** a query point  $\mathbf{q}$  and data structure  $\mathcal{T} = \{T_1, \dots, T_L\}$

**Output:** a set  $\mathcal{S}$  of nearest neighbours of  $\mathbf{q}$

```

1:  $\mathcal{S} \leftarrow \emptyset$ 
2: for each  $g_l \in \{g_1, \dots, g_L\}$  do
3:    $\mathcal{S}_l \leftarrow T_l[g_l(\mathbf{q})]$ 
4:   if  $|\mathcal{S}_l| > 0$  then
5:     for each  $\mathbf{p}_n \in \mathcal{S}_l$  do
6:       if  $d(\mathbf{p}_n, \mathbf{q}) \leq cr$  then
7:         add  $\mathbf{p}_n$  to  $\mathcal{S}$ 
8: return  $\mathcal{S}$ 

```

Algorithm 2: LSH Query

Answering a query point  $\mathbf{q}$  is done by hashing it multiple times for each  $g_l$  as in the preprocessing step (see Algorithm 2). Each time, the set of points  $\mathcal{P}$ , stored in the corresponding hash table  $T_l$  at the slot  $g_l(\mathbf{q})$ , are retrieved. That is, identify all  $\mathbf{p}_n$ , such that  $g_l(\mathbf{p}_n) = g_l(\mathbf{q})$ . For each identified  $\mathbf{p}_n$ , a distance function evaluates if the distance  $d(\mathbf{p}_n, \mathbf{q})$  is within the search perimeter  $cr$ . If positive, the point is added to the result set  $\mathcal{S}$ , which is returned at the end of the algorithm.

With regard to preprocessing, the consideration of space complexity of Algorithm 1 is interesting, whereas the runtime of Algorithm 2 is the most relevant when examining the execution of queries. Fortunately, lower bounds on both quantities have been proven in [MNP06], from which the optimization of the parameters  $K$  and  $L$  can be derived. Without giving details on the derivation of the results, the algorithm complexity is as follows. By ignoring lower order terms, the algorithm exhibits a query time of  $O(N^\rho)$  and a space complexity of  $O(N^{1+\rho})$ . Thus, the query time and space consumption improves significantly as  $\rho$  is decreased. The parameter  $\rho$  is introduced as the main parameter that determines the running time and space consumption of the algorithm.

### 2.2.3 Random Projection

This section presents a specific technique that is a locality-sensitive hashing function. The algorithm that bases on this technique is known as Gaussian Random Projection (GRP). This approach utilizes the cosine similarity of two real vectors in order to determine their similarity. In the course of this section, basic definitions for Cosine Distance and Cosine Similarity are introduced. Then, the individual calculation steps of the approach are specified. Finally, a visual proof verifies that GRP is a form of LSH.

Figure 2.9: Illustration of a random hyperplane partitioning the space

The cosine distance can be applied in euclidean spaces and discrete versions of euclidean spaces [LRU14, p. 95]. For two real vectors  $\mathbf{p}_1$  and  $\mathbf{p}_2$ , the cosine distance between is equal to the angle between  $\mathbf{p}_1$  and  $\mathbf{p}_2$ , regardless of the dimensionality of the space. Note, that by applying the arc-cosine function, the result is in the range  $[0, 180]$ . The following definition formalizes what has been stated so far.

**Definition 6** (Cosine Distance). Given two vectors  $\mathbf{p}_1$  and  $\mathbf{p}_2$ , the cosine distance  $\theta(\mathbf{p}_1, \mathbf{p}_2)$  is the dot product of  $\mathbf{p}_1$  and  $\mathbf{p}_2$  divided by their euclidean distances from the origin ( $L_2$ -norm):

$$\theta(\mathbf{p}_1, \mathbf{p}_2) = \cos^{-1} \left( \frac{\mathbf{p}_1^\top \mathbf{p}_2}{\|\mathbf{p}_1\| \|\mathbf{p}_2\|} \right). \quad (2.5)$$

The angle  $\theta$  can be normalized to the range  $[0, 1]$  by dividing it by  $\pi$ . This way, the cosine similarity is simply given by the following definition.

**Definition 7** (Cosine Similarity). The cosine similarity is computed as

$$1 - \frac{\theta(\mathbf{p}_1, \mathbf{p}_2)}{\pi} \quad (2.6)$$

Introduced in [Cha02], the GRP is defined as follows. Given a point  $\mathbf{p} \in \mathcal{P} \subset \mathbb{R}^D$  and a randomly selected hyperplane defined as  $\mathbf{M} = (a_{ij}) \in \mathbb{R}^{D \times K}$  where  $a_{ij} \sim \mathcal{N}(0, I)$ , a *gaussian random projection (GRP)* aims to (I) reduce the dimensionality from  $D$  to  $K$  dimensions and (II) provide a binary encoding by first projecting  $\mathbf{p}$  onto  $\mathbf{M}$  and subsequently applying the sign function to each element of the result, which can be formalized as

$$h(\mathbf{p}) = [h(\mathbf{p}, a_1), \dots, h(\mathbf{p}, a_K)] \text{ with } h(\mathbf{p}, a_k) = \text{sign}(\mathbf{p}^\top a_k) \quad (2.7)$$

$$\text{with } \text{sign}(x) = \begin{cases} 0 & \text{if } x < 0, \\ 1 & \text{if } x \geq 0. \end{cases} \quad (2.8)$$

Figure 2.10: Visual Proof of claim in equation 2.9

An illustration of a random hyperplane that dissects the three-dimensional space and partitions the data space is given in Figure 2.9. The resulting digest is a binary vector  $h(\mathbf{p}) = \mathbf{b} \in \mathcal{B}$  with  $\mathcal{B} = \{0, 1\}^K$  that is used as bucket index for storing  $\mathbf{p}$  in a hash table. For any two messages  $\mathbf{p}_1, \mathbf{p}_2$ , the probability of being hashed to the same bucket increases with a decreasing distance, given as

$$P[h(\mathbf{p}_1) = h(\mathbf{p}_2)] = 1 - \frac{\theta(\mathbf{p}_1, \mathbf{p}_2)}{\pi}. \quad (2.9)$$

For a visual proof of the claim in Equation 2.9 consider Figure 2.10, where two vectors  $\mathbf{p}_1$  and  $\mathbf{p}_2$ , regardless of their dimensionality, define a plane and an angle  $\theta$  in this plane. Pick a hyperplane  $E_1$  that intersects the plane that is spanned by  $\mathbf{p}_1$  and  $\mathbf{p}_2$  in a line (depicted as a red dashed line), by randomly selecting a corresponding normal vector  $\mathbf{n}_1$ . Since  $\mathbf{p}_1$  and  $\mathbf{p}_2$  are on different sides of the hyperplane, their projections given by  $\mathbf{p}_1^\top \mathbf{n}_1$  and  $\mathbf{p}_2^\top \mathbf{n}_1$  will have different signs. Such a scenario, where two points have different signs, is interpreted as a notion of dissimilarity. Thus, the hyperplane acts as a clustering primitive that partitions the original input set into two disjunct sets.

The opposite scenario is illustrated by a random normal vector  $\mathbf{n}_2$  that is normal to the hyperplane  $E_2$ , which is represented by the blue dashed line. Both  $\mathbf{p}_1^\top \mathbf{n}_2$  and  $\mathbf{p}_2^\top \mathbf{n}_2$  will have the same sign. This in turn is interpreted as a notion of similarity, since both points are clustered into the same set. All angles between the intersection line of the random hyperplane and the plane spanned by  $\mathbf{p}_1$  and  $\mathbf{p}_2$  are equally likely. Thus, the probability that the hyperplane looks like the red line is  $\theta/\pi$  and like the blue line  $1 - \theta/\pi$ .

Therefore, the GRP is a  $(r, cr, (1 - r/\pi), (1 - cr/\pi))$ -sensitive family for any  $r$  and  $cr$ . As already explained in Section 2.2.2, such a family can be amplified as desired. The AND-construction refers to the selection of a number of  $K$  different random hyperplanes  $r_k$ . According to the construction in Equation 2.7, all projections  $\text{sign}(\mathbf{p}_n^\top \mathbf{n}_k)$  for a single point are collected in a  $K$ -bit vector. Likewise, the OR-construction refers to the initialization of a number of  $L$  such AND-constructions. The algorithmic procedures for preprocessing and queries from Algorithm 1 and Algorithm 2 can be applied without change.

## 2.3 Gaussian Mixtures

GMMs refer to a density estimation technique in the machine learning context. With the help of density estimation techniques, large amounts of data can be compactly represented in a model. An estimate of important characteristics of an unobservable probability density function, such as mean or variance, is constructed based on the observed data. The density function is considered as the distribution according to which the observed data population is distributed. In the context of this work, GMMs are used for the compact representation of attack data. Instead of exchanging the datasets directly in the CIDS, the data is instead represented by gmms, whereupon their parameters are shared. In this way, the data volume of the CIDS communication is significantly reduced. The GMM can be considered as a generative model, since new data can be generated by ancestral sampling. Thus, by reconstructing the GMMs from the shared parameters, the generation of synthetic data in the respective local infrastructures can be enabled. This data can in turn be used flexibly in the context of improving the respective intrusion detection.

For that purpose, important basics and concepts are introduced in this section. First, the Gaussian normal distribution is presented in Section 2.3.1 as the GMM is based on that parametric family. Then, in Section 2.3.2 mixture models in general and GMMs in particular are defined. Lastly, in Section 2.3.3 the GMM is interpreted in terms of a Latent Variable Model (LVM) and the Expectation Maximization Algorithm (EM Algorithm) is presented, which performs the computation of model parameters of latent variable models in an iterative scheme.

### 2.3.1 The Gaussian Distribution

The Gaussian normal distribution forms the basic building block for GMMs. Depending on the observed random variable, different types of normal distributions exist. In particular, the multivariate normal distribution is focused on when considering statistical flow features, which are typically continuous and high dimensional. In the following, different definitions for the normal distribution are introduced and important properties are presented that are essential for calculations during the learning phase of GMMs.

Let be a multivariate random variable  $\mathbf{X} = (X_1, \dots, X_D)^\top$ , where each element  $X_d$  with  $d \in \{1, \dots, D\}$ ,  $D \in \mathbb{N}$  is a univariate random variable that follows a normal distribution, which is referred to as  $X_d \sim \mathcal{N}(\mu, \sigma^2)$ . In [DFO20, p. 175], the univariate and multivariate Gaussian is defined as follows.

**Definition 8** (Univariate Gaussian Distribution). A continuous, univariate random variable  $X$  is said to follow a normal distribution, if it exhibits a probability density function

$$p(x|\mu, \sigma^2) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left(-\frac{(x-\mu)^2}{2\sigma^2}\right),$$

with  $x \in \mathbb{R}$  and where  $\mu$  refers to the mean and  $\sigma^2$  is the variance of the distribution. Then, if  $\mathbf{X}$  follows a normal distribution, this is expressed as a multivariate Gaussian distribution, denoted by  $\mathbf{X} \sim \mathcal{N}_D(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ , which is fully described by its mean vector  $\boldsymbol{\mu}$  and its covariance matrix  $\boldsymbol{\Sigma}$ .

Figure 2.11: Bivariate gaussian distributions exhibit different shapes with a changing correlation value between the random variables  $x_1$  and  $x_2$ : (a) negative, (b) zero and (c) positive correlation

**Definition 9** (Multivariate Gaussian Distribution). A multivariate random variable  $\mathbf{X}$  follows a normal distribution, if it is described by a probability density function

$$p(\mathbf{x}|\boldsymbol{\mu}, \boldsymbol{\Sigma}) = (2\pi)^{-\frac{D}{2}} |\boldsymbol{\Sigma}|^{-\frac{1}{2}} \exp\left(-\frac{1}{2}(\mathbf{x} - \boldsymbol{\mu})^T \boldsymbol{\Sigma}^{-1}(\mathbf{x} - \boldsymbol{\mu})\right),$$

with  $\mathbf{x} \in \mathbb{R}^D$ . The mean vector  $\boldsymbol{\mu}$  specifies the estimate of the expected value of the distribution, with each of its components describing the mean  $\mu$  of the corresponding dimension. The empirical covariance  $\boldsymbol{\Sigma}$  models the estimate of the variance along each dimension as well as the correlation between the different dimensions. The diagonal elements of  $\boldsymbol{\Sigma}$  describe the variance of the random variable corresponding to the respective dimension and the off-diagonal elements describe the covariance relationship between the respective random variables. An illustration of the influence of the described parameters on the location and shape of a multivariate distribution is given in Figure 2.11. Specifically, three bivariate normal distributions are considered, whose random variables each have different values with respect to their correlation, while the mean vector is the same for all distributions.

Having introduced the basic definition of Gaussian distributions, it is now examined how they can be manipulated to obtain information necessary for parameter learning of Gaussian mixture models. Two practical algebraic properties of normal distributions, namely closure under *conditioning* and *marginalization* are detailed for this purpose. Being closed under conditioning and marginalization in this case means that when one or more components of a Gaussian distribution is marginalized out or conditioned on, that the resulting distribution is still Gaussian. This not only distinguishes Gaussian distributions from other distributions, but also makes them easier to handle mathematically. Since both marginalization and conditioning act on subsets of the original distribution, the following notation is introduced first. Considering a multivariate Gaussian random variable  $\mathbf{X} \sim \mathcal{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma})$  with  $\mathbf{X}_M \in \mathbf{R}^M$ , where  $M < N$ , and  $\mathbf{X}_N \in \mathbf{R}^N$ , where  $N = D - M$ , we partition  $\mathbf{X}$  according to

$$\mathbf{X} = \begin{bmatrix} \mathbf{X}_M \\ \mathbf{X}_N \end{bmatrix}.$$

In general,  $\mathbf{X}_M$  is chosen to be the first  $M$  elements of  $\mathbf{X}$  and  $\mathbf{X}_N$  the rest. Accordingly,  $\boldsymbol{\mu}$  and  $\boldsymbol{\Sigma}$  are partitioned as

$$\begin{bmatrix} \mathbf{X}_M \\ \mathbf{X}_N \end{bmatrix} \sim \mathcal{N} \left( \begin{bmatrix} \boldsymbol{\mu}_M \\ \boldsymbol{\mu}_N \end{bmatrix}, \begin{bmatrix} \boldsymbol{\Sigma}_{MM} & \boldsymbol{\Sigma}_{MN} \\ \boldsymbol{\Sigma}_{NM} & \boldsymbol{\Sigma}_{NN} \end{bmatrix} \right).$$

With this form, it is now possible to express the extraction of partial information from multivariate probability distributions by means of marginalization. In [DFO20, p. 177], the marginal of a Gaussian is defined as follows.

**Definition 10** (Marginal of a Gaussian Distribution). Given  $\mathbf{X} \sim \mathcal{N}_D(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ , with partitions  $\mathbf{X}_M, \mathbf{X}_N$ , the distributions of  $\mathbf{X}_M$  and  $\mathbf{X}_N$  are called marginals and their corresponding probability density function can be obtained by

$$p(\mathbf{x}_M) = \int p(\mathbf{x}_M, \mathbf{x}_N) d\mathbf{x}_N.$$

Furthermore, each partition  $\mathbf{X}_M, \mathbf{X}_N$  only depend on its corresponding entries in  $\boldsymbol{\mu}$  and  $\boldsymbol{\Sigma}$ . The authors in [DFO20, p. 177] state that the marginal of a Gaussian is also a Gaussian, which is determined by

$$\mathbf{X}_M \sim \mathcal{N}(\boldsymbol{\mu}_M, \boldsymbol{\Sigma}_{MM}).$$

The conditional Gaussian is typically utilized in the context of posterior distributions, such as in the process of density estimation of GMMs, and is defined in [DFO20, p. 177] as follows.

**Definition 11** (Conditional of a Gaussian Distribution). Given  $\mathbf{X} \sim \mathcal{N}_D(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ , with partitions  $\mathbf{X}_M, \mathbf{X}_N$ , the conditional distribution is defined as

$$\begin{aligned} p(\mathbf{x}_M | \mathbf{x}_N) &= \mathcal{N}(\boldsymbol{\mu}_{M|N}, \boldsymbol{\Sigma}_{M|N}), \\ \boldsymbol{\mu}_{M|N} &= \boldsymbol{\mu}_M + \boldsymbol{\Sigma}_{MN} \boldsymbol{\Sigma}_{NN}^{-1} (\mathbf{x}_N - \boldsymbol{\mu}_N), \\ \boldsymbol{\Sigma}_{M|N} &= \boldsymbol{\Sigma}_{MM} - \boldsymbol{\Sigma}_{MN} \boldsymbol{\Sigma}_{NN}^{-1} \boldsymbol{\Sigma}_{NM}. \end{aligned}$$

Accordingly, the conditional distribution of a Gaussian distribution is also a Gaussian [DFO20, p. 177], which is defined by

$$\mathbf{X}_{M|N} \sim \mathcal{N}(\boldsymbol{\mu}_{M|N}, \boldsymbol{\Sigma}_{M|N}).$$

A line of arguments proving the stated theorems can be found in section 2.3 in [Bis06]. An example for marginal and conditional Gaussians can be found in Figure 2.12. The functions of  $p(\mathbf{x}_M)$  and  $p(\mathbf{x}_N)$  are plotted on the side grids.

Figure 2.12: Marginals  $p(x_M)$ ,  $p(x_N)$  and Conditional Gaussian  $p(x_{M|N})$

### 2.3.2 The Gaussian Mixture Model

Using statistical estimation techniques, it is possible to estimate an unobservable underlying probability density function from observed data. This allows data to be compactly represented with a density from a parametric family, such as a Gaussian distribution. However, all conventional parametric distributions are limited in their modeling capabilities when confronted with real data. For example, considering data that follows a multimodal distribution, i.e., have more than one center, a density estimate using a simple Gaussian distribution is not sufficient to effectively represent data distribution.

The idea is to represent a multimodal distribution by constructing a linear combination of multiple simple distributions, each of which representing a unimodal sub-population of the data, which is formalized under the term *mixture model* [Bis06, p.111].

**Definition 12** (Mixture Model). A mixture model is a linear combination of  $K$  parametric distributions  $p_k$ , where each distribution is weighted by a mixture weight  $w_k$ , defined as

$$p(x) = \sum_{k=1}^K w_k p_k(x),$$

$$0 \leq w_k \leq 1, \sum_{k=1}^K w_k = 1.$$

A distribution  $p_k$  within this model is called mixture component and the sum of the mixture weights equals to 1, such that the probability density of the mixture components equals to 1 as well.

Mixture Models can use any arbitrary parametric distribution as component density, but the most common mixture model is the Gaussian mixture model, using Gaussians as components [HTF09, p. 214]. First, GMMs utilize the practical mathematical properties of Gaussians, introduced earlier in Section 2.3.1.

Furthermore, the quality of the model, in terms of its ability to estimate real data distributions, is theoretically supported by the Central Limit Theorem, which states that most data distributions converge to a normal distribution on average as the number of data points increases [JB03, p.222]. The Central Limit Theorem is stated as follows [MR10, p. 241].

**Definition 13** (Central Limit Theorem). Consider  $N$  i.i.d. random variables  $X_i$  with  $\mathbb{E}[X_i] = \mu$  and  $\mathbb{V}[X_i] = \sigma^2$  and let  $S_N = \sum_{i=1}^N X_i$ . It can be shown that, as  $N$  increases, that

$$p(S_N) \sim \mathcal{N}\left(\mu, \frac{\sigma^2}{N}\right).$$

By further specifying the general definition of mixture models (see Definition 12), we obtain the definition of a GMM (see Definition 14). Instead of using an arbitrary parametric distribution as the component density, the Gaussian distribution is utilized. Furthermore, the set of parameters  $\boldsymbol{\theta}$  of the GMM is introduced.

**Definition 14** (Gaussian Mixture Model). A Gaussian Mixture Model is a combination of a finite number of  $K$  Gaussian distributions  $\mathcal{N}(\mathbf{x}|\theta_k)$  which is fully described by a probability density function  $p$  and its parameter set  $\boldsymbol{\theta}$  as

$$\begin{aligned} p(\mathbf{x} | \boldsymbol{\theta}) &= \sum_{k=1}^K w_k \mathcal{N}(\mathbf{x} | \theta_k), \\ 0 \leq w_k \leq 1, \sum_{k=1}^K w_k &= 1, \\ \boldsymbol{\theta} &= (\theta_1, \dots, \theta_K), \theta_k = (\boldsymbol{\mu}_k, \boldsymbol{\Sigma}_k, w_k). \end{aligned} \tag{2.10}$$

### 2.3.3 The Expectation Maximization Algorithm

So far, with the definition and the example, an intuitive explanation of the GMM has been given. Before it is explained how to estimate the parameters of the model, it is necessary to look at the subject from the perspective of probabilistic modeling. Probabilistic models, in general, utilize the mathematics of probability theory in order to express all forms of uncertainty and noise that is associated with the learning task. If a Bayesian interpretation is thereby applied to the probabilities, then this is commonly referred to as Bayesian Inference. This allows, for example, the estimation of the parameters of a probability distribution or a statistical model utilizing Bayes' Theorem [DFO20, p.245]. In this case, discrete latent variables must be introduced into the construction, which allows a probabilistic model to be formed by defining a joint distribution over observed variables and latent variables [Bis06, p. 432].

The term latent variable usually refers to a variable that cannot be observed directly, but can be inferred from other observable variables using mathematical models [BMH03]. Models involving such latent variables, called LVM, are usually harder to fit than models without latent variables, but often have fewer parameters due to their natural implication of a bottleneck, resulting in a compressed representation of the data [Mur12, p. 337].

For simplicity, first a single data point  $\mathbf{x}$  is considered, which is later expanded to a set of data points  $\mathcal{X} := \{\mathbf{x}_1, \dots, \mathbf{x}_N\}$ ,  $\mathcal{X} \subset \mathbb{R}^D$ . It is further assumed a GMM with  $K$  components. Thus, a  $K$ -dimensional binary random variable  $\mathbf{z}$  is introduced.

Note that  $\mathbf{z} = [z_1, \dots, z_K]^\top$  indicates whether the  $k$ th mixture component is responsible for generating the data point  $\mathbf{x}$  and that a data point can only be generated by one mixture component. Hence, only a particular element  $z_k$  is equal to one and all other elements are equal to zero, such that

$$z_k \in \{0, 1\}, \quad \sum_{k=1}^K z_k = 1. \quad (2.11)$$

For the construction of a probabilistic model, it is necessary to specify the joint distribution of the observed data  $\mathbf{x}$  and the latent variable  $\mathbf{z}$ . Therefore, the factors of the joint distribution are defined as

$$p(\mathbf{x}, \mathbf{z}) = p(\mathbf{z})p(\mathbf{x}|\mathbf{z}). \quad (2.12)$$

The responsibility of mixture component  $k$  generating a data point  $\mathbf{x}$  can be expressed as the conditional distribution of  $\mathbf{x}$  given a specific assignment for  $\mathbf{z}$ , which is a Gaussian

$$p(\mathbf{x}|z_k = 1) = \mathcal{N}(\mathbf{x}|\boldsymbol{\mu}_k, \boldsymbol{\Sigma}_k) \quad \Rightarrow \quad p(\mathbf{x}|\mathbf{z}) = \prod_{k=1}^K \mathcal{N}(\mathbf{x}|\boldsymbol{\mu}_k, \boldsymbol{\Sigma}_k)^{z_k}. \quad (2.13)$$

In practice, there exists no knowledge about the value assignment of the latent variables. Therefore, a prior is set to  $\mathbf{z}$ , which is defined as

$$p(\mathbf{z}) = \mathbf{w} = [w_1, \dots, w_K]^\top, \quad \sum_{k=1}^K w_k = 1. \quad (2.14)$$

Now, there is a way to describe the *probability* that the  $k$ th mixture component generated the data point  $\mathbf{x}$  as

$$p(z_k = 1) = w_k. \quad (2.15)$$

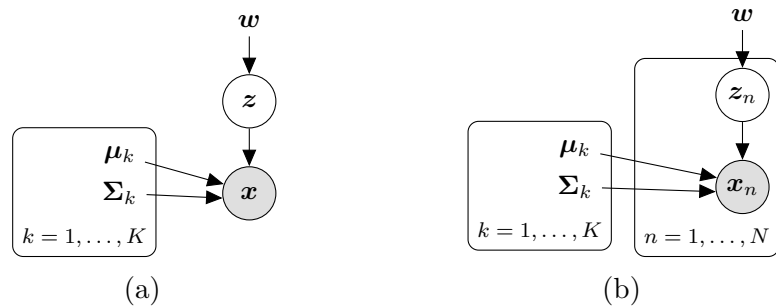

Figure 2.13: Both graphs represent a GMM using plate notation. While the left graph (a) includes a single data point  $\mathbf{x}$ , the graph on the right side (b) extends the model to a full dataset with  $N$  i.i.d. data points  $\{\mathbf{x}_n\}$  and corresponding latent variables  $\{\mathbf{z}_n\}$ . Note, that the directed edge from the latent variable to the observed data reflects the joint distribution from (2.12).

Then the conditional distribution  $p(\mathbf{x}|\mathbf{z})$  from (2.13) and the prior distribution  $p(\mathbf{z})$  from (2.14) are plugged into the joint distribution  $p(\mathbf{z})p(\mathbf{x}|\mathbf{z})$  from (2.12) and the marginal distribution  $p(\mathbf{x})$  is obtained by summing the joint distribution over all possible states of  $\mathbf{z}$ , which results in

$$p(\mathbf{x}) = \sum_{\mathbf{z}} p(\mathbf{z})p(\mathbf{x}|\mathbf{z}) = \sum_{k=1}^K w_k \mathcal{N}(\mathbf{x}|\boldsymbol{\mu}, \boldsymbol{\Sigma}). \quad (2.16)$$

It can be summarized that the GMM has been extended by including the discrete latent variable  $\mathbf{z}$  and that the result is still consistent with the previous definition, since the marginal distribution  $p(\mathbf{x})$  is a Gaussian mixture of the form (2.10). This enables the joint distribution  $p(\mathbf{x}, \mathbf{z})$  to be used in place of the marginal distribution  $p(\mathbf{x})$ , greatly simplifying parameter estimation by applying the EM Algorithm.

So far, it was assumed that the dataset consists of a single data point  $\mathbf{x}$ . Now, the dataset is extended to  $N$  data points. From that, it follows that every data point  $\mathbf{x}_n$  possesses its own latent variable  $\mathbf{z}_n$ . All latent variables can be summarized by  $\mathcal{Z} \subset \mathbb{R}^K$ . This extension to a full dataset is also illustrated comparatively in Figure 2.13. In accordance to that, the corresponding posterior probability after observing  $\mathbf{x}$ , referred to as  $r_{nk}$ , is obtained using Bayes' Theorem as

$$\begin{aligned} r_{nk} &= p(z_{nk} = 1|\mathbf{x}_n) = \frac{p(z_{nk} = 1)p(\mathbf{x}|z_k = 1)}{p(\mathbf{x})} \\ &= \frac{p(\mathbf{x}_n)|z_{nk} = 1)p(z_{nk} = 1)}{\sum_{j=1}^K w_j p(\mathbf{x}_n|z_{nj} = 1)p(z_{nj} = 1)} \\ &= \frac{w_k \mathcal{N}(\mathbf{x}_n|\boldsymbol{\mu}_k, \boldsymbol{\Sigma}_k)}{\sum_{j=1}^K w_j \mathcal{N}(\mathbf{x}_n|\boldsymbol{\mu}_j, \boldsymbol{\Sigma}_j)}. \end{aligned} \quad (2.17)$$

The posterior  $r_{nk}$  can be interpreted, from the perspective of a generative model, as the proportion with which a component is involved in the generation of the point  $\mathbf{x}_n$ .

The central question is how to fit the set of unknown parameters  $\boldsymbol{\theta}$  to a given set of data  $\mathcal{X}$  and therefore finding a good approximation for the unknown distribution  $p(\mathbf{x})$ . For estimation problems based on i.i.d. data points, the Maximum Likelihood Estimation (MLE) is an applicable method [DFO20, p. 317]. By doing this, the likelihood of each data point  $\mathbf{x} \in \mathcal{X}$  given a specific parametrization  $\boldsymbol{\theta}$  is maximized. To do so, the likelihood function, and the log-likelihood function respectively, must first be constructed, where each individual likelihood term is a Gaussian mixture density as

$$\begin{aligned} p(\mathcal{X}|\boldsymbol{\theta}) &= \prod_{n=1}^N p(\mathbf{x}_n|\boldsymbol{\theta}), \quad p(\mathbf{x}_n|\boldsymbol{\theta}) = \sum_{k=1}^K w_k \mathcal{N}(\mathbf{x}_n|\boldsymbol{\mu}, \boldsymbol{\Sigma}), \\ \log p(\mathcal{X}|\boldsymbol{\theta}) &= \sum_{n=1}^N \log p(\mathbf{x}_n|\boldsymbol{\theta}) = \underbrace{\sum_{n=1}^N \log \sum_{k=1}^K w_k \mathcal{N}(\mathbf{x}_n|\boldsymbol{\mu}, \boldsymbol{\Sigma})}_{=:\mathcal{L}}. \end{aligned}$$

The common solution scheme that would follow would be to calculate the gradient  $\partial\mathcal{L}/\partial\boldsymbol{\theta}$ , set it to zero and solve for  $\boldsymbol{\theta}$ . Unfortunately, there is no closed form solution for a MLE in this form, because the summation over the  $K$  components prevents the logarithm from being applied to the Gaussian densities within [Bis06, p. 435]. That means that each of the partial derivatives of the model parameters depends on all  $K$  parameters of the GMM through  $r_{nk}$ , which prohibits a closed form solution.

However, a solution can be found using the EM Algorithm. The key idea here is to update one model parameter at a time while keeping the others fixed. For that, the ML estimators for the individual parameters of the GMM are required first, which will be applied in the EM Algorithm in the following step. The following necessary conditions are established:

$$\begin{aligned}\frac{\partial\mathcal{L}}{\partial\boldsymbol{\mu}_k} = \mathbf{0}^T &\iff \sum_{n=1}^N \frac{\partial\log p(\mathbf{x}_n|\boldsymbol{\theta})}{\partial\boldsymbol{\mu}_k} = \mathbf{0}^\top \\ \frac{\partial\mathcal{L}}{\partial\boldsymbol{\Sigma}_k} = \mathbf{0} &\iff \sum_{n=1}^N \frac{\partial\log p(\mathbf{x}_n|\boldsymbol{\theta})}{\partial\boldsymbol{\Sigma}_k} = \mathbf{0} \\ \frac{\partial\mathcal{L}}{\partial w_k} = 0 &\iff \sum_{n=1}^N \frac{\partial\log p(\mathbf{x}_n|\boldsymbol{\theta})}{\partial w_k} = 0.\end{aligned}$$

In the following only the partial derivatives of the model parameters that will be used in the EM Algorithm are presented. A detailed calculation can be found in [DFO20, pp.319].

$$\begin{aligned}\boldsymbol{\mu}'_k &= \frac{\sum_{n=1}^N r_{nk} \mathbf{x}_n}{\sum_{n=1}^N r_{nk}} \\ \boldsymbol{\Sigma}'_k &= \frac{1}{N_k} \sum_{n=1}^N r_{nk} (\mathbf{x}_n - \boldsymbol{\mu}_k)(\mathbf{x}_n - \boldsymbol{\mu}_k)^\top \\ w'_k &= \frac{N_k}{N}\end{aligned}\tag{2.18}$$

The EM Algorithm is an iterative procedure that starts with an initial estimate of the parameters, which are updated incrementally until convergence is detected. The initial values for the parameters can either be chosen randomly or obtained with an heuristic method, e.g. by using k-means to cluster the data first and subsequently defining the weights based on the resulting k-means memberships [DFO20, pp. 325].

Each iteration  $t$  of the EM Algorithm consists mainly of two steps, the Expectation step and the Maximization step. A third step is subsequently needed for the calculation of the convergence criterion. First, in the expectation step, the posterior distribution  $r_{nk}$  from (2.17) is calculated for all data points  $\mathbf{x}_n$  with the current set of parameters  $\boldsymbol{\theta}^{(t)}$ . Then, the posterior from the previous step is used in the maximization step for computing the new parameter values with the Maximum-Likelihood estimators defined in (2.18). At the end of each iteration, the log likelihood for the new set of parameters  $\boldsymbol{\theta}^{(t+1)}$  and its change from the log likelihood from the previous iteration is computed. Then, the algorithm can test for convergence by comparing  $\Delta\mathcal{L}$  with the convergence threshold  $\epsilon$  and the algorithm stops if no significant change occur anymore.

**Initialize:**

- 1:  $t = 0$
- 2:  $\boldsymbol{\theta}^{(t)} := \{\boldsymbol{\mu}_k, \boldsymbol{\Sigma}_k, w_k \mid k = 1, \dots, K\}$
- 3:  $\mathcal{L}^{(t)} = \log p(\mathcal{X} \mid \boldsymbol{\theta}^{(t)})$
- 4: **while**  $\Delta\mathcal{L} > \epsilon$  **do**
  1. Expectation-Step:
  - 5:  $r_{nk} = \frac{w_k \mathcal{N}(\mathbf{x}_n \mid \boldsymbol{\mu}_k, \boldsymbol{\Sigma}_k)}{\sum_{j=1}^K w_j \mathcal{N}(\mathbf{x}_n \mid \boldsymbol{\mu}_j, \boldsymbol{\Sigma}_j)}$  with  $\boldsymbol{\theta}^{(t)}$
  2. Maximization-Step:
  - 6:  $w_k^{(t+1)} = \frac{N_k}{N}$
  - 7:  $\boldsymbol{\mu}^{(t+1)} = \frac{\sum_{n=1}^N r_{nk} \mathbf{x}_n}{\sum_{n=1}^N r_{nk}}$
  - 8:  $\boldsymbol{\Sigma}_k^{(t+1)} = \frac{1}{N_k} \sum_{n=1}^N r_{nk} (\mathbf{x}_n - \boldsymbol{\mu}_k)(\mathbf{x}_n - \boldsymbol{\mu}_k)^\top$
  - Convergence Terms:
  - 9:  $\mathcal{L}^{(t+1)} = \log p(\mathcal{X} \mid \boldsymbol{\theta}^{(t+1)})$
  - 10:  $\Delta\mathcal{L} = |\mathcal{L}^{(t+1)} - \mathcal{L}^{(t)}|$
  - 11:  $t = t + 1$

Algorithm 3: EM Algorithm for GMM

Figure 2.14 illustrates the EM Algorithm for fitting a GMM with three components on a two-dimensional synthetic dataset with three classes. Each component of the GMM is represented by an coloured ellipse, that is formed by its mean and covariance matrix. Every single data point  $\mathbf{x}_n$  is associated with an probability vector, that describes each component's responsibility for creating  $\mathbf{x}_n$ . A data point is assigned to the component that exhibits the highest responsibility value. This is visualized by coloring each data point according to their assignment to a component. In this example, the three component parameters are chosen randomly and no posterior  $r_{nk}$  is computed in the beginning ( $t = 0$ ) and thus no data point is colored. In this state, the true class labels can be seen in different grayscale.

Figure 2.14: Illustration of the EM algorithm for fitting a GMM with three components on a two-dimensional dataset.

With each iteration, the parameters approach the local optimum, which they reach after iteration 21 ( $t = 21$ ), and the algorithm converges. In this toy example, the three classes can be separated well by three components. Note that multiple components may describe a single class as well. This raises the question of how many components should be ideally chosen for fitting a GMM, when the number of classes are not known beforehand as in this example?

A common method is to select the model with the highest probability given the data  $\mathcal{X}$ . Recall that the likelihood  $\mathcal{L}$  answers the question of what is the probability that  $\mathcal{X}$  is explained by the model. Theoretically, in the case of a GMM, one could just arbitrarily increase the number of components  $K$  until  $K = N$  in order to obtain the maximum likelihood. In practice, this would not only lead to a bad runtime of the algorithm, but also overfit the model. Thus, the maximum likelihood of the model  $\mathcal{L}$  has to be balanced against the number of model parameters. The bayesian information criterion (BIC) is considered as a standard criterion for GMM model selection because of its theoretical consistency in choosing the number of components [Ker00]. Let  $|\boldsymbol{\theta}|$  be the number of model parameters in general, then the BIC is defined as

$$\text{BIC} = |\boldsymbol{\theta}| \ln(N) - 2 \ln(\mathcal{L}), \quad (2.19)$$

which derives from the findings in [Sch78]. The BIC balances the number of model parameters  $|\boldsymbol{\theta}|$  and number of data points  $N$  against the likelihood function  $\mathcal{L}$ . In the model selection, the optimal number of model parameters  $|\boldsymbol{\theta}|$  minimizes the BIC, such that it provides a principled way of selecting between multiple different models. More complex models almost always fit the data better, resulting in a lower value for the term  $-2 \ln(\mathcal{L})$ . The BIC penalizes extra parameters by introducing the term  $|\boldsymbol{\theta}| \ln(N)$ . A model selection utilizing the BIC is described in Algorithm 4, with  $\boldsymbol{\theta}$  being the set of parameter settings for GMM.

**Input:** Dataset  $\mathcal{X}$

**Output:** Gaussian Mixture Model GMM

```

1:  $L_{\text{GMM}} \leftarrow$  new List
2: for each  $\theta$  in  $\boldsymbol{\theta}$  do
3:    $\text{GMM}_k \leftarrow \text{fitGaussianMixture}(\mathcal{X}, \theta)$ 
4:    $\text{BIC}_k \leftarrow \text{computeBIC}(\text{GMM}_k | \mathcal{X})$ 
5:   append ( $\text{GMM}_k, \text{BIC}_k$ ) to  $L_{\text{GMM}}$ 
6: sort  $L_{\text{GMM}}$  ascending by  $\text{BIC}_k$ 
7:  $\text{GMM} \leftarrow L_{\text{GMM}}[0]$  ► get head of the list
8: return GMM
```

Algorithm 4: GMM Selection with BIC

To be more precisely, the parameters of  $K$  multivariate normal distributions are to learn. With  $D = \dim(\mathcal{X})$ , these are  $D$  values in the mean vector. Since a covariance matrix is symmetric, only  $D(D + 1)/2$  entries in a full covariance matrix have to be computed. Additionally,  $K$  mixture weights have to be determined, leading to  $Kd + K(d(d + 1)/2) + K$  parameters. Thus, the BIC for a dataset  $\mathcal{X}$  with  $N$  datapoints of dimensionality  $D$  and a GMM as defined above is stated as

$$\text{BIC}(\text{GMM} | \mathcal{X}) = (KD + K(D(D + 1)/2) + K) \ln(N) - 2 \ln(\mathcal{L}). \quad (2.20)$$

## 2.4 Principal Component Analysis

This chapter focuses on dimensionality reduction of data in the context of Principal Component Analysis (PCA). First, the application of dimensionality reduction in general is motivated by various examples. Then, the core idea based on the separation of signal and noise in data is presented. After this, a concrete statement of the problem is introduced. In addition, key model assumptions and a solution approach is presented and followed by a mathematical derivation of the eigencomposition for solving PCA.

### 2.4.1 Motivation

Several difficulties arise when analyzing high-dimensional data [DFO20, p.286]. For example, it is often not easy to interpret which of the many factors have the most significant influence on the data distribution. In addition, data visualizations are often limited to a few dimensions. And besides the impact on data analysis, there are also influences on data inference. Some machine learning algorithms cannot effectively reason about the underlying structure of the data in high-dimensional space, which can result into a model overfitting. Furthermore, compression of data, in terms of dimensionality reduction, can lead to advantages in processing and persistence of data. Data storage can often come at a high cost and some algorithms do not scale well with increasing numbers of dimensions. For example, when using the EM Algorithm (see Section 2.3.3) an increase of the dimensionality of the data is related to an increase in the probability of the occurrence of (nearly) singular matrices, which can result in a numerical breakdown of the model [Bis06, p.434]. For these reasons, dimensionality reduction is often desired within a data preprocessing strategy.

In general, dimensionality reduction methods make use of the following idea. Measuring data is error prone and associated with both incompleteness and redundancy. This trend increases with the number of dimensions. Thus, many dimensions in multivariate data can be explained by a combination of other dimensions. This underlying structure can be exploited by partitioning the full space into subspaces of signal and noise [Sco15, p. 217]. Figure 2.15 shows two synthetic datasets each with two features. The plot on the right displays a negative correlation and the direction that carries the largest portion of the signal can be located visually.

Figure 2.15: Two synthetic datasets illustrating the difference in signal and noise

In this two-dimensional example, the direction that is perpendicular to that is the direction that carries the least amount of signal and is referred to as noise. The goal is to discard a significant amount of noise in the data and work with a more compact representation, with losing as little signal as possible.

### 2.4.2 Problem Description

All data points  $\mathbf{x}_n$  can be represented as a linear combination of the orthonormal basis. The central question associated with PCA is whether there is another basis, which is a *linear* combination of the original basis, that best represents the data. From this perspective, PCA can be considered a change-of-basis problem. Recalling the example from Figure 2.15, a better representation of the data is related to a lower amount of noise and redundancy in the data. Further, by assuming linearity, the problem is simplified by restricting the set of potential bases and enabling an efficient solution with matrix decomposition techniques [Sh14]. Note that it is not always the case that the correlation among variables is not of interest. But in the case of PCA, correlation represents redundancy, which is desired to be minimized.

To derive a solution approach, some assumptions are made beforehand, which are proven in the following section. It is assumed that data containing more redundancy generally have lower variance and vice versa. Therefore, the dynamics of interest exist in the directions of highest variance. It is further assumed that the canonical basis in which the data was captured is a representation that has inherent redundancies and noise. For this reason, a suitable basis is searched that represents a linear transformation of the canonical basis, such that the base aligns with the axes of maximum variance of the data. By projecting the data onto the axis of maximum variance, which form a lower-dimensional subspace, data redundancy is eliminated.

Finding the directions of maximum variance, which are referred to as principal components, is the central operation of PCA. One feasible option is to diagonalize the covariance matrix of the data. Recalling that each covariance matrix is a square symmetric matrix whose off-diagonal elements represent the covariances, i.e., reflect the redundancies, a diagonalization of the covariance matrix eliminates the magnitude of the covariance, resulting in a matrix that only contains the variance terms. Finally, each successive dimension in the diagonalized covariance matrix should be rank-ordered according to the values of the variance in order to quantify their importance. It can be shown that the principal components are the eigenvectors of the covariance matrix of the data. A frequently used method for solving PCA is therefore the eigendecomposition, which is mathematically derived in the following in connection with the assumptions made so far.

### 2.4.3 Formal Description

Consider a dataset  $\mathcal{X} = \{\mathbf{x}_1, \dots, \mathbf{x}_N\} \in \mathbb{R}^D$  with mean  $\mathbf{0} = [0_1, \dots, 0_N]^\top$  and a covariance matrix

$$\Sigma = \frac{1}{N} \sum_{n=1}^N \mathbf{x}_n \mathbf{x}_n^\top.$$

In terms of dimensionality reduction, a compressed representation of the dataset  $\mathcal{X}$ , where each datapoint is defined as

$$\mathbf{z}_n = \mathbf{B}^\top \mathbf{x}_n \in \mathbb{R}^M$$

is searched for, which retains as much signal as possible [Hot33]. This is done by finding a linear transformation

$$\mathbf{B} = [\mathbf{b}_1, \dots, \mathbf{b}_M] \in \mathbb{R}^{D \times M}$$

that projects  $\mathcal{X}$  onto the subspace that is spanned by the columns of  $\mathbf{B}$ . Thus,  $\mathbf{B}$  is an orthonormal basis. In order to preserve the most variance of the data, the basis vectors of  $\mathbf{B}$  must point into the direction of maximal variance in the data, which is found by computing the eigenvectors of the covariance matrix  $\mathbf{\Sigma}$  of  $\mathcal{X}$ . The projection of the data onto a lower-dimensional subspace is equal to the eigenvalue that is associated with the basis vector that spans this subspace.

Therefore, maximizing the variance of the low-dimensional representation requires to choose the basis vector that is associated with the largest eigenvalue of the data covariance matrix. This eigenvector is called the first principal component. All other directions in  $\mathbb{R}^M$ , which both maximize the variance and are orthogonal to all the other directions are the remaining  $M - 1$  principal components.

As stated before, the projection matrix  $\mathbf{B}$  is obtained by diagonalizing the covariance matrix  $\mathbf{\Sigma}$ , which can be done via eigendecomposition. In the following, it is shown how the eigendecomposition is related to the diagonalization of a matrix and that an eigendecomposition of a covariance matrix is guaranteed to exist. In [DFO20, p. 98] it is stated that a matrix  $\mathbf{A} \in \mathbb{R}^{N \times N}$  is diagonalizable if it is similar to a diagonal matrix, i.e., if there exists an invertible matrix  $\mathbf{P} \in \mathbb{R}^{N \times N}$  such that  $\mathbf{D} = \mathbf{P}^{-1} \mathbf{A} \mathbf{P}$ .

In [DFO20, p. 99] it is stated that with an Eigendecomposition a square matrix  $\mathbf{A} \in \mathbb{R}^{N \times N}$  can be factorized into

$$\mathbf{A} = \mathbf{P} \mathbf{D} \mathbf{P}^{-1}, \quad (2.21)$$

where  $\mathbf{P} \in \mathbb{R}^{N \times N}$  and  $\mathbf{D}$  is a diagonal matrix whose entries are the eigenvalues of  $\mathbf{A}$ , if and only if the eigenvectors of  $\mathbf{A}$  form a basis of  $\mathbb{R}^n$ .

It follows, that only non defective matrices can be diagonalized. In other words, a square matrix that does not have a complete basis of eigenvectors is not diagonalizable. However, the Spectral Theorem (see Definition 15) confirms the existence of such a basis for symmetric matrices [DFO20, p. 94].

**Definition 15** (Spectral Theorem). If  $\mathbf{A} \in \mathbb{R}^{N \times N}$  is symmetric, there exists an orthonormal basis of the corresponding vector space consisting of eigenvectors of  $\mathbf{A}$ , and each eigenvalue is real.

From the fact that every covariance matrix is symmetric, we conclude that a symmetric matrix  $\mathbf{S} \in \mathbb{R}^{n \times n}$  can always be diagonalized.

Therefore, it is assured that an eigendecomposition of a symmetric matrix  $\mathbf{A}$  exists (with real values), and that an ONB of eigenvectors can be found, so that  $\mathbf{A} = \mathbf{P}\mathbf{D}\mathbf{P}^{-1}$ , where  $\mathbf{D}$  is diagonal and the columns of  $\mathbf{P}$  contain the eigenvectors. Rewriting the equation from Theorem 2.21 as follows reveals the eigenvalue equations:

$$\mathbf{A}[p_1, \dots, p_N] = [p_1, \dots, p_N] \begin{bmatrix} \lambda_1 & 0 & 0 & \cdots & 0 \\ 0 & \lambda_2 & 0 & \cdots & 0 \\ 0 & 0 & \lambda_3 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & \lambda_N \end{bmatrix} \iff \begin{array}{lcl} \mathbf{A}p_1 & = & \lambda_1 p_1 \\ \mathbf{A}p_2 & = & \lambda_2 p_2 \\ \mathbf{A}p_3 & = & \lambda_3 p_3 \\ & \cdots & \\ \mathbf{A}p_N & = & \lambda_N p_N \end{array}$$

Next, it is shown how the eigenvalue equation shown above is related to the maximization of the variance of the data. For this purpose, the single vector  $\mathbf{b}_1 \in \mathbb{R}^D$  is considered only, which is the first column of the matrix  $\mathbf{B}$  and therefore the first of  $M$  orthonormal basis vectors. By exploiting the i.i.d. assumption of the data, the first component of  $\mathbf{z}_n \in \mathbb{R}^M$  of a single data point  $\mathbf{x}_n \in \mathbb{R}^D$  is given by

$$z_{1n} = \mathbf{b}_1^\top \mathbf{x}_n. \quad (2.22)$$

Thus,  $z_{1n}$  is the coordinate of the orthogonal projection of  $\mathbf{x}_n$  onto the one-dimensional subspace spanned by  $\mathbf{b}_1$ . Then, the variance of  $z_{1n}$  of  $\mathbf{z} \in \mathbb{R}^M$ , that is maximized by  $\mathbf{b}_1$ , is defined as

$$\mathbb{V}_1 := \mathbb{V}[z_1] = \frac{1}{N} \sum_{n=1}^N z_{1n}^2. \quad (2.23)$$

The relation between the variance and the factorized matrix in Equation 2.21 becomes evident by substituting Equation 2.22 into Equation 2.23 as

$$\begin{aligned} \mathbb{V}_1 &= \frac{1}{N} \sum_{n=1}^N (\mathbf{b}_1^\top \mathbf{x}_n)^2 \\ &= \frac{1}{N} \sum_{n=1}^N \mathbf{b}_1^\top \mathbf{x}_n \mathbf{x}_n^\top \mathbf{b}_1 \\ &= \mathbf{b}_1^\top \left( \frac{1}{N} \sum_{n=1}^N \mathbf{x}_n \mathbf{x}_n^\top \right) \mathbf{b}_1 \\ &= \mathbf{b}_1^\top \Sigma \mathbf{b}_1. \end{aligned} \quad (2.24)$$

Maximizing the variance defined in Equation 2.24 results in finding vector  $\mathbf{b}_1$ . But arbitrarily increasing the magnitude of  $\mathbf{b}_1$  increases  $\mathbb{V}_1$ , which is why restricting all solutions to unit vector size is necessary:

$$\|\mathbf{b}_1\|^2 = 1 \Leftrightarrow \|\mathbf{b}_1\| = 1.$$

Restricting the solution space results into a constrained optimization problem, given as

$$\begin{aligned} \max \quad & \mathbf{b}_1^\top \mathbf{\Sigma} \mathbf{b}_1 \\ \text{s.t.} \quad & \|\mathbf{b}_1\|^2 = 1. \end{aligned}$$

Applying the method of Lagrange multipliers, the new objective function is obtained as

$$\mathcal{L}(\mathbf{b}_1, \lambda) = \mathbf{b}_1^\top \mathbf{\Sigma} \mathbf{b}_1 + \lambda_1(1 - \mathbf{b}_1^\top \mathbf{b}_1).$$

The partial derivative of  $\mathcal{L}$  with respect to  $\mathbf{b}_1$  gives

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial \mathbf{b}_1} &= 2\mathbf{b}_1^\top \mathbf{\Sigma} - \lambda_1 \mathbf{b}_1^\top \\ 0 &= 2\mathbf{b}_1^\top \mathbf{\Sigma} - \lambda_1 \mathbf{b}_1^\top \\ \mathbf{\Sigma} \mathbf{b}_1 &= \lambda_1 \mathbf{b}_1. \end{aligned}$$

By the definition shown above,  $\mathbf{b}_1$  has to be an eigenvector of  $\mathbf{\Sigma}$  with the lagrangian multiplier as corresponding eigenvalue. Then, computing the derivative with respect to  $\lambda_1$  results in

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial \lambda_1} &= 1 - \mathbf{b}_1^\top \mathbf{b}_1 \\ 0 &= 1 - \mathbf{b}_1^\top \mathbf{b}_1 \\ \mathbf{b}_1^\top \mathbf{b}_1 &= 1. \end{aligned}$$

Finally, the variance objective from Equation 2.24 can be rewritten as

$$\mathbb{V}_1 = \mathbf{b}_1^\top \mathbf{\Sigma} \mathbf{b}_1 = \lambda_1 \mathbf{b}_1^\top \mathbf{b}_1 = \lambda_1. \quad (2.25)$$

The variance of the projected data equals the eigenvalue that is related to the basis vector  $\mathbf{b}_1$ , which spans the subspace the data is projected onto. In other words, the eigenvector that is associated with the biggest eigenvalue  $\lambda_1$  is the first principal component.

Since the vector  $\mathbf{b}_1^\top$  is considered a linear transformation, computing its inverse projects  $z_{1n}$  back into the original data space  $\mathbb{R}^D$ , such that

$$\tilde{\mathbf{x}}_n = \mathbf{b}_1 z_{1n} = \mathbf{b}_1 \mathbf{b}_1^\top \mathbf{x}_n.$$

So far, only the solution for the first principal component has been derived. Generalizing this schema onto a  $M$ -dimensional subspace with maximal variance involves some way of mathematical induction. The idea is to subtract the effect of the first  $M - 1$  principal components  $\mathbf{b}_1, \dots, \mathbf{b}_{M-1}$  from the data and thereby trying to find the principal components that compress the remaining information. For a detailed investigation of this general case, reference is made to [DFO20, pp.291]

# Chapter 3

## Related Work

This chapter presents related work organized in three categories. First, data dissemination in CIDS is reviewed in Section 3.1. Two interesting approaches are examined in detail. Based on this, the main challenges in this domain are summarized. Second, Section 3.2 addresses the topic of similarity hashing in intrusion detection. In this context, the similarities and differences between approximate matching and LSH are first discussed. This is followed by a broad overview of various approaches that use similarity hashing in the context of intrusion detection. Third, section 3.3 investigate which use cases exist for generative algorithms in the field of intrusion detection. Finally, the main features of the presented approach are comparatively summarized based on the focus areas that appear in the related work in Section 3.3.

### 3.1 Data Dissemination in CIDS

Among the key components of a CIDS described in Section 2.1.3, data dissemination is particularly noteworthy as one of the fundamental mechanisms for the communication between members. A central aspect is the communication *overhead* that is introduced with the dissemination of information within a CIDS, which in turn is heavily influenced by the CIDS architecture [Vas16, p.39]. The data dissemination strategy of a CIDS not only defines the communication paths as described above, but also influences what kind of data is exchanged between the CIDS members while also specifying format and level of granularity. This also includes the central aspects of *data privacy*, realized by utilization of, e.g., bloom filters [Vas+15][Loc+05], and *interoperability* that can be obtained by standardized formats, such as the Intrusion Detection Message Exchange Format (IDMEF) [DCF07]. For example, the architecture in [CM02] implements an alert base management function that receives alert messages from different IDS which are subsequently stored for further analysis. It is assumed that the messages are compliant with the IDMEF. Messages are converted into a set of logical facts and stored in a relational database upon reception, such that a correlation function can operate on the data. Another example is the P2P overlay IDS, presented in [Dum+06]. Here, different isolated IDS cooperate within a P2P network in order to collectively detect attacks. Upon an attack, a node warns its peers about that attack with a warning message. To assure interoperability the IDMEF is employed for sending warning messages. In the context of communication overhead, there are two approaches in particular to mention. In [Loc+05], the authors present an approach for the efficient and privacy aware distribution of alert data in a distributed CIDS. Before exchanging information, the respective data is compressed by the utilization of a bloom filter data structure. Upon an alert, the relevant information, e.g. IP address, is inserted into the bloom filter. Since the bloom filter contains information on suspicious hosts, it is called *watchlist*. The watchlist is shared among peers, which are selected by a network scheduling algorithm called *whirlpool*, that dynamically creates an overlay that defines peer relationships. The authors mention two challenges in the context of data dissemination. First, sharing sensitive information is not an option, thus preventing participation in the CIDS. Second, the tradeoff between latency of information exchange and the reliability of the exchange must be balanced. Centralized approaches disseminate information reliable and predictable, but they constitute a bottleneck. While distributed approaches scale well, information can be lost or delayed by partitioning the data among the peers. In the context of reducing communication overhead, this approach addresses this challenge twofold. First, alert data is compressed when inserted into the bloom filter by hashing. Second, only peers exchange data, which reduces overhead significantly, when compared to a complete distribution. However, bloom filters are a probabilistic data structure, that exhibits an increasing false positive rate with an increasing filling degree. Thus, when scaling this approach, the probability that innocent hosts are considered as malicious, increases. Furthermore, the authors in [Vas+15] state, that a CIDS needs to provide *scalability*, minimal message *overhead*, *privacy* of the exchanged alert data, an *domain awareness*, which describes the ability to constrain alert dissemination to specific sub-domains of a network. Instead of randomly creating sub-domains as in [Loc+05], the authors suggest to incorporate network traffic similarities into account for this process. The communication within this approach is done within a P2P overlay network.

First, specific features from alerts are extracted and added into a bloom filter. Then, a defined data dissemination technique (e.g. flooding, partial flooding, gossiping) is utilized for sending bloom filters to other nodes. When a node receives data, it computes a similarity value by performing logical operations on the respective bloom filters. By doing so, each sensor creates a matrix with its local knowledge of other sensors. Based on this knowledge and along with a similarity threshold, sensors can identify similar nodes and form a community with them to, afterwards, exchange more fine-grained alert data. One problem in this approach is finding an optimal value for the similarity threshold. Furthermore, the formation of communities could be generalized if the similarity threshold did not depend on specific alerts, but rather on the general network characteristics of an infrastructure. To sum up, four challenges are considered to be essential in the context of data dissemination in CIDS. First, the computational overhead introduced by the communication of multiple monitors in the CIDS needs to be minimized, such that potential knowledge gains are available fast enough. Second, members may not want to disclose data that contains information on system- and network states of their infrastructure, as it constitutes a privacy and security problem. This includes, among other things, legal aspects when it comes to sharing log and network data. Nonetheless, the exchange of this information is crucial for the effective operation of a CIDS. Furthermore, interoperability is constitutional as the individual members in the CIDS should be able to interact with each other. Lastly, the aspect of domain awareness supports the minimization of overhead. By constraining the flow of information, the communication volume is decreased, while at the same time ensuring the dissemination to relevant members.

## 3.2 Similarity Hashing in Intrusion Detection

With the term similarity hashing we summarize all methods that are known by the name approximate matching or LSH, although there are more or less subtle differences in these approaches. Nonetheless, this section presents works in the field of intrusion detection using methods that belong to the category of similarity hashing. First, the differences between the two methods are briefly described. Starting with LSH, recall from Section 2.2.2 that this is an algorithm for solving the  $c$ -ANNP which exhibits strong theoretic assumptions. Furthermore, it solves the problem by clustering data points according to a given distance measure, which in fact defines the similarity. Approximate matching functions, on the other hand, are designed to identify similarities between two objects by creating digests of the respective objects and comparing them with each other. Approximate matching functions are not only capable of finding objects that resemble each other but also find objects that are contained in another object [Bre+14]. Note that existing definitions are blurry and hybrid constructions, such as TLSH, which is an algorithm that uses LSH to build an approximate matching function [OCC13], also exist. The field of cyber security has adopted methods for similarity search, mainly for the analysis of polymorphic malware. This type of malware poses a significant challenge, since it changes its appearance over time in order to stay undetectable from antivirus software [WM18, p.91]. Traditional antivirus software uses cryptographic hash functions in order to create file signatures. Such signatures are well suited to search for identical files in a knowledge database. However, due to the property of cryptographic diffusion of cryptographic hash functions, even minimal changes to the malware result in large differences in the resulting hash value.

With the rapid evolution and proliferation of polymorphic malware, detection based on unique signatures no longer seems effective. Based on these developments, detection schemes using approximate matching functions have initially become the focus of research. Popular approaches in this area are for example *ssdeep* or *sdhash*. Ssdeep [Kor06] is an established algorithm for malware detection as it is supported by the malware analysis repository VirusTotal<sup>1</sup>. Ssdeep implements context triggered piecewise hashing (CTPH), which is a form of block-based hashing. Block-based hashing separates the data into fixed-size blocks, that are hashed individually, commonly by a non-cryptographic hash function. The final digest results from the concatenation of all hashes. The similarity of two digests can then be measured by comparing the number of common blocks. Existing algorithms mainly differentiate by their approach for the block construction. In particular, ssdeep uses a rolling hash to create variable-sized blocks. A sliding window moves through the input and produces specific outputs based on the current bytes in the window. Using these values, trigger points that indicate the boundaries of a block are identified. Sdhash [Rou10] extracts so-called features using a fixed-size sliding window that moves through the input. After calculating the shannon entropy for all extracted features, the lowest values within a defined interval are selected and hashed using SHA-1. The digest is split into five subhashes that are used to insert the respective feature into a bloom filter. As soon as a bloom filter reaches its capacity, a new one is initialized and used to store hashes. The final digest is the sequence of all bloom filters. Sdhash compares two objects by comparing each filter from the first object with every filter from the second object. Besides similarity detection, sdhash is also capable of detecting containment of certain sequences within objects. Instead of using digests for a similarity search directly, the authors in [LP19b] employ LSH for feature extraction in the context of malware classification. In this approach, similarity hashing algorithms are applied on javascript files that contain malware in form of obfuscated malicious code. The resulting hashes are used as input for a neural network that serves as a classifier. Within another work, LSH is used for instance selection on an intrusion detection dataset [BH21]. Instance selection identifies a subset of the original dataset whose application for the model training results in a similar or even increased performance as if the entire dataset had been used. An improved model performance can usually be achieved, when the reduction of samples results in a reduction of noise in the dataset. The authors identify that the main issue for the applicability of instance selection algorithms in IDS is the computational complexity of established algorithms. By incorporating an algorithm based on LSH that is presented in [AS20], redundant samples are defined as samples whose similarity to a given instance exceeds a defined threshold. By removing redundant samples, the volume of the dataset is decreased significantly while the detection performance has remained the same or is even improved. However, neither the authors in [BH21] nor those in [AS20] describe the construction of the hash function used to assign a bucket index to a sample. Motivated by the vast growth of malware samples, the authors in [OCN14] present a fast algorithm for clustering malware into limited number of malware families, which are easier to manage than single samples. In particular, LSH is employed for the clustering on a large collection of malware samples. Although the algorithm is still quadratic in theory, the authors state that the coefficient for the quadratic term is several orders of magnitude smaller. The algorithm was tested on a collection of over one million malware samples, which is not further described.

### 3.3 Generative Algorithms and Intrusion Detection

In the area of intrusion detection, generative algorithms primarily demonstrate their typical strengths, such that the ability to compensate for underrepresented classes with synthetic data generated by the generative model is by far the most frequent application. For example, the authors in [Yan+19] present a network intrusion detection architecture in which a deep convolutional generative adversarial networks (DCGAN) is used to generate synthetic network intrusion data in order to balance the original training data. A multichannel SRU-based model is used as discriminative model for the classification task. The employed data for the experiments is versatile and includes the KDD99 dataset [Het99], the NSL-KDD dataset [Tav+09] and the CIC-IDS2017 dataset [SHG18]. Evaluation results for both binary and multiclass classification show improvements regarding the employed metrics compared to the performance of common classification algorithms. However, the authors neglect to state parameter settings for the algorithms which were used for comparison and do not incorporate alternative upsampling algorithms in the experiments. In contrast to that, the authors in [HL20] compare their approach to common classification algorithms in combination with alternative balancing methods, namely random under-sampling, random over-sampling and SMOTE [Cha+02]. The presented architecture also employs a GAN for generating synthetic samples in the context of upsampling minority classes in the training data. Multiclass classification experiments were conducted using the NSL-KDD dataset [Tav+09], the CIC-IDS2017 dataset [SHG18] and the UNSW-NB15 dataset [MS15]. Furthermore, the robustness of the approach is evaluated in detail by incrementally increasing the class imbalances in the experimental setup by random under-sampling. Although there is a slight downward trend in performance with increasing imbalance, the approach remains relatively stable. Another example is the architecture in [LP19a], where a feature extraction precedes the upsampling process by using an Autoencoder to transform statistical network flow features into a low-dimensional representation, which serve as input for the training of a CGAN. In all the stated approaches, the balancing of minority classes using generative algorithms leads to an increase in detection performance, compared to experiments without class balancing or with alternative balancing methods. However all these approaches do not incorporate an evaluation of the synthetic data before including them into the training data. The authors in [Sha+20] present an interesting approach for evaluating synthetic data within their framework. There, the synthetic data is categorized into synthetic and pending data. Data flagged as synthetic is already verified and stays permanently in the database. The verification of the pending data depends on the decision of a controller module. Within the training phase, two classifier models are trained. The first model is trained on real and synthetic data and the second model is trained on real, synthetic and pending data. If the second model performs better than first model, the controller accepts the pending samples and flags them as synthetic. Otherwise the pending samples are rejected and removed from the database. Besides the utilization of generative algorithms for oversampling in intrusion detection, there are also other interesting applications. Some approaches employ GANs for synthesizing adversarial attack traffic that is used to evade an IDS, whose internal structure and parameters are unknown. For example, the authors in [LSX22] state that the goal of the architecture is to generate malicious feature records similar to the attack traffic which can bypass the detection of the IDS. Then, attackers derive attack design principles for IDS evasion from the synthetic records.

From a technical perspective, in order to maintain specific functional features of attacks within the sample generation, specific attack attributes remain unaltered while nonfunctional features are fine-tuned in order to trick the classifier of the IDS. However, it has to be ensured that an adversarial perturbation does not invalidate the features used for intrusion detection. The approach presented in [Usa+19] also includes a training mechanism for defense purposes that increases the robustness of the IDS against adversarials. Specifically, an adversarial training [Sze+13] is conducted, in which the detection model learns the possible adversarial perturbations by training on clean and adversarial examples. Another application derives from the field of distributed learning of deep neural networks. The authors in [FS19] leverage a distributed-learning architecture in order to share attack information among multiple IDS without the requirement of sharing real data samples. In particular, a GAN is trained by deploying multiple discriminators at different entities that act as the detection unit. The feedback of the discriminators within the training phase is aggregated to a central generator model that incrementally creates a global perspective without exchanging real data. It is shown that each participating discriminator performs well in the evaluation and the central generator represents a global collection of local datasets. However, while in the training phase, the generator has to send synthetic data to each of the participating discriminators. Furthermore the approach is tested on a daily activity recognition dataset [Rey+16], which does not represent an intrusion detection dataset. Furthermore, besides malicious traffic also benign traffic of each local dataset is combined into the global knowledge which potentially introduces a significant amount of noise.

### 3.4 Main Distinguishing Features

The presented approach achieves scalability and reduces overhead in two ways. First, LSH is used to partition the input data in order to achieve data parallelism. By leveraging a cloud native implementation elastic scaling for serving bursty workloads is enabled. Second, the data volume is reduced significantly by representing it in the form of generative models before distributing it in the CIDS. Exchanging model parameters only maintains data privacy. Sampling synthetic data from a generative model is considered as the decompression operation, enabling the full feature set instead of working on hashed data for privacy reasons. Furthermore, the approach does not implement a distributed P2P overlay but can rather be considered centralized from a logical perspective. However, a redundant and distributed implementation ensures scalability and availability. Data dissemination is realized by synchronizing local and global data stores using an event-based application architecture. This means that updates on local data stores are sent first to the global data store, resulting in the output of events that are in turn distributed to local data stores. Upon the reception of an event, a local data store fetches the new global state. As events are sent via a messaging service, the consistency between different local data stores depends on the implemented messaging service. Consistency between data stores and their replicas depend on the implemented data store. Hence, data consistency can be considered differentiated on these two levels. The presented approach is not conform to the IDMEF, because the information exchange is decoupled from the detection process. Each local intrusion detection dataset is enhanced using synthetic data from the exchanged generative models, including the advantage of data balancing. The respective intrusion detection is mainly independent and is only committed to a globally defined feature set.

## Chapter 4

# Generative Pattern Database

Three main challenges in the context of data dissemination in CIDS were identified. First, intrusion related data is usually of sensitive nature. Thus, the exchange mechanism must not compromise any policies and regulations related to data *privacy*. At the same time, the usability of the data has to be preserved. Second, the data that is subject of the exchange may exhibit large volumes. That constitutes a challenge, since the dissemination is desired to be executed with *minimal overhead* in a timely and scalable fashion. Lastly, the *interoperability* of the CIDS with existing local IDS is an important aspect that influences the practical adoption into security architectures. In summary, existing approaches for data dissemination mainly provide mechanisms for exchanging alert data or single attributes, e.g. IP addresses, as they focus on the correlation of intrusion detection incidents that originate from different sensors. The exchange of actual training data is neglected, possibly due to high data volumes. Thus, these systems lack of mechanisms for the extraction and global persistence of novel attack patterns, e.g. from zero day exploits, that can be used for the training of an intrusion detection sensor.

The approach that is presented in this chapter exchanges attack patterns by sharing generative machine learning models that have been trained on partitions of similar data points. Such a model-based dissemination enables the receiving side to sample a synthetic dataset that enhances existing local datasets. This provides two main advantages. First, no original data leaves a local network and therefore does not violate any privacy restrictions. Second, the data is compressed considerably by representing it in form of a generative model. In order to make that mechanism scalable, the monitored data is clustered using random projections. This way, similar data points are partitioned into globally common clusters, which is exploited as a data parallelism mechanism. Given that, bursty workloads can be served effectively in a cloud deployment. Furthermore, this mechanism enables a similarity-based correlation of distributed intrusion events. The integration of both a similarity based correlation of intrusion incidents and a mechanism for sharing attack knowledge makes it possible to extract novel patterns of distributed attacks and provide them globally within the CIDS, resulting in an improved attack detection.

Section 4.1 introduces the idea and key concepts of the approach. After that, Section 4.2 specifies the proposed architecture in detail. A comprehensive description of algorithms and processing steps are described in Section 4.3.

Figure 4.1: Example integration of the generative pattern database into a generic NIDS deployment, separated by data and detection level

## 4.1 High Level Overview

Several members exist in the CIDS, each of which manages an isolated IDS. Every IDS operates according to a specific set of rules, that is essentially based on the content of a local database. The goal of the generative pattern database is to close the knowledge gaps of local databases and thus increase the detection rate of associated IDSs. By providing a *global view* on all local databases, individual IDSs can benefit from the collective knowledge of the CIDS.

Section 4.1.1 starts with a reference example to illustrate the idea that is described above and discusses the integration of the CIDS into existing infrastructures. Subsequently, Section 4.1.2 and Section 4.1.3 show the key concepts that enable data distribution and correlation under the given requirements. Finally, Section 4.1.4 combines the individual elements to present the strategy for the creation and utilization of the global view.

### 4.1.1 Example Integration

An exemplary integration of the CIDS into a generic NIDS is shown in Figure 4.1. The exemplary NIDS deployment consists of three components, that can be found on the detection layer. A flow exporter computes statistical flow features based on the network packets of a switch. A discriminative model serves as a classifier that operates on the specific feature set that the exporter extracts. After completing the training of a classifier instance on a given dataset, it is deployed within the detection pipeline. There, the classifier receives a stream of network flows and predicts them.

The CIDS mainly integrates at the data level, where the training data for the classifier is provided by the *local pattern database*. At this point, the local pattern database only contains the *local view* of the intrusion detection data from that particular member. In order to provide a global view, a synchronization process between its local pattern database and the *global pattern database* has to be initiated. Before the data is transferred to the global pattern database, it is subject to a set of clustering, filtering and compression operations. This way, data privacy is maintained and overhead is minimized by reducing the data volume.

On the receiving side, the global pattern database combines data from all members into a global view. Upon each update of the global pattern database, the new state of the global view is synchronized to each local pattern database and subsequently enhances the classifier on the detection level by extending the local intrusion detection dataset. Furthermore, an identical clustering operation as on the data level is applied on the detection level. Each incoming flow is assigned to a certain cluster, which is referred to as *region*. While the predictions from the classifier are suitable for detecting attacks that are known to the CIDS, regions are leveraged for the detection of novel data patterns and similarity-based correlations that uncover large-scale coordinated attacks, which are executed on the resources of multiple CIDS members simultaneously.

### 4.1.2 Clustering

The clustering operation has to meet certain requirements in this approach. First, the results of the clustering operation should be consistent while it is executed among all members of the CIDS in a distributed fashion. Additionally, the algorithm should be scalable, since it is to be applied on whole databases on the data level and on streams of live data on the detection level. Given these requirements, gaussian random projection (GRP) (see Section 2.2.3) is selected. By using GRP, real data points are clustered according to their angular distance. Furthermore, the projection result is a binary string, which can be used for storing similar data points into a common bucket of a hash table by using the binary string as an index. In the context of the generative pattern database, the combination of GRPs and hash tables is exploited as the main controlling primitive for data persistence and retrieval. Instead of using randomly selected projection planes, a shared seed results in the application of a common projection function among all members of the collaboration. In other words, similar data points from different datasets are indexed to a common global bucket, i.e. region. Each region is subject to the transformations individually, which is utilized as a data parallelism mechanism. Thus, this approach is natively suited for cloud deployments where bursty workloads can be served effectively by balancing the load on an arbitrary number of instances. Lastly, this mechanism enables a similarity-based correlation of distributed intrusion events. As incoming data is monitored on the detection level, the clustering is applied, which results in a pattern that can be used for novelty checks or global occurrences within the CIDS.

### 4.1.3 Filtering and Compression

Two types of data are extracted within individual regions. First, metadata of local datasets is collected by counting label occurrences, which serve as indicator for determining if the respective region needs to be subject to the second extraction type. Second, models that are trained with generative algorithms on local attack data are the exchange medium for disseminating information within the CIDS. This provides two main advantages. For one, no original data leaves a local network and therefore does not violate any privacy restrictions. For another, the data is compressed considerably by representing it in form of a generative model.

### 4.1.4 Global View

As shown in Figure 4.2, each view is partitioned by a common projection function into an identical set of regions. Each local view contains original datapoints from the local dataset of the respective CIDS member. In this example, there exist three different classes globally, which occur differently in each local dataset. Examining a specific region, the combination of unique classes within all local views determines its complexity on a global level. For instance, the yellow region (global view) is simple, because within all local views, there occurs only a single class. A complex region in the global view, on the other hand, is formed by the occurrence of multiple classes within the same region in all local views. If a region in the global view contains more than one class, it potentially exhibits a non-linear decision boundary, hence it is called complex. This complexity information is distributed to all members of the CIDS by tagging the corresponding local regions with the complexity state of the region from the global view. After that, all local regions that are tagged as complex are modeled by a generative algorithm by using the corresponding local data points as training data. Subsequently, the resulting models are transferred to the global view. A synchronization process disseminates the region complexity estimations and the generative models to all local views. Within each local view, data points are sampled from generative models which are subsequently assembled into a synthetic dataset. Finally, the synthetic datasets are blended into the respective local datasets for enhancing the subsequent training of discriminative models.

Figure 4.2: Building the global view by combining  $M$  local views

## 4.2 Architecture Specification

Logically, the proposed CIDS exhibits a hierarchical architecture (see Figure 4.3). For one, the global infrastructure  $G$  represents the collection of  $M$  CIDS participants and their knowledge on an abstract level. For another, it provides specific services, that are globally available to each local infrastructure  $L_m, m \in \{1, \dots, M\}$  that includes all CIDS components and services within the IT infrastructure boundaries of a corresponding CIDS member. Each local infrastructure  $L_m$  agrees to a specified feature extraction process that provides the monitoring data  $\mathcal{X} \subset \mathbb{R}^D$  with a total number of features  $D = \dim(\mathbf{x})$  for the attack detection. As the deployed NIDS is considered to be a supervised classification task, the ultimate goal is to find an approximation of an unknown target function  $c : \mathcal{X} \rightarrow \mathcal{Y}$  that maps samples  $\mathbf{x} \in \mathcal{X}$  to classes  $y \in \mathcal{Y}$ . In order to find an approximation  $\hat{c} \sim c$ , an individual training dataset  $\mathcal{D}_m = \{(\mathbf{x}_n, y_n) : 1 \leq n \leq N_m\}$  of size  $N_m = |\mathcal{D}_m|$  is provided in every  $L_m$ . True target values  $c(\mathbf{x}) = y$  are given by the domain expert that assembled  $D_m$ . In addition, in the CIDS network, a common  $\mathcal{Y}$  is agreed upon, so that there is a global consensus on class memberships.

CIDS communication across local boundaries occurs exclusively in a vertical direction. Thus, the exchange of information between individual  $L_m$  takes place indirectly via the global pattern database ( $PDB_G$ ) and the global event channel ( $C_G$ ). Each  $L_m$  includes a local pattern database ( $PDB_{L_m}$ ), a local event channel ( $C_{L_m}$ ) and an event-based data processing pipeline that consists of four services, namely *Local Indexing*, *Complexity Estimation*, *Generative Fitting* and *Classifier Fitting*.

Each instance of a pattern database ( $PDB$ ) is realized as a key-value store and depending on the scope different tasks are considered. Each  $PDB_{L_m}$  is responsible for storing  $D_m$  and corresponding metadata. The  $PDB_G$  stores global metadata and the generative models that resemble the original data from each  $D_m$ . The notation for operations on a  $PDB$  corresponds to the notation for hash table operations defined in Section 2.2.2. Note, that if a locality-sensitive hash function is used to construct a key, in practice a hash table will internally apply a non-cryptographic hash function on the key to ensure an even distribution of the keys across the slots.

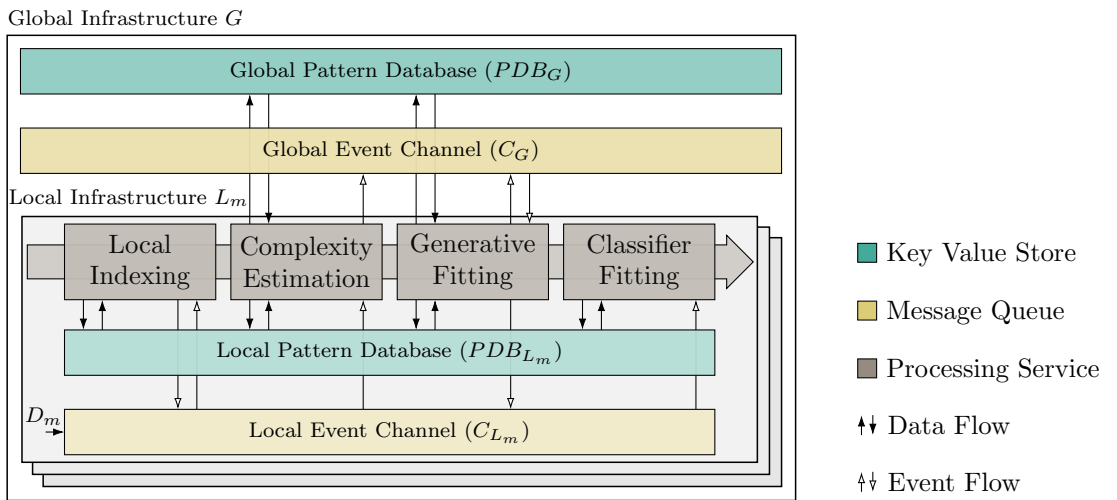

Figure 4.3: CIDS architecture illustrating the data and event flow between components within and across local infrastructure boundaries

Nonetheless, the clustering of neighbouring points into common slots is still ensured in this scenario. Each event channel  $C$  provides a topic-based publish-subscribe messaging mechanism that is mainly used to instantiate and distribute workloads among the service instances in the processing pipeline. Via the messaging system, service instances receive and emit events, on which upon the respective operations are triggered. Changes in a  $PDB$  result in responses that in turn are leveraged as the respective events. In this fashion, updates are propagated throughout the processing pipeline, ensuring a timely consistency among the pattern databases.

## 4.3 Service Specification

In Section 4.1, the roles of the clustering, filtering and compression operations within the architecture and the idea of the global view have been roughly explained. These concepts are implemented within the processing pipeline that has been referred to in Section 4.2 as four consecutive and event-based services, which are described in detail by focusing on a single service in each subsection.

### 4.3.1 Local Indexing

The local indexing service is responsible for the preprocessing and local storage of  $D_m$ . As already described in Section 4.1.2, the data is organized in regions. This means that individual data points are first assigned to a region using a GRP. By doing that, a hash of the data point is computed. Based on the generated hash value, a key is constructed that is used to persist that data point in the respective  $PDB_{L_m}$ . According to the properties of a locality-sensitive hash function, similar data points are assigned to a common region and thus form a closed processing unit for subsequent operation steps. If a region is initialized or an update is made to an existing region, e.g., due to the occurrence of new data, events are emitted to inform the subsequent service.

First, an intrusion detection dataset  $D_m$  is sent to one or more service processors via the  $C_{L_m}$ . Second, the incoming stream of pairs of data points and labels  $(\mathbf{x}_n, y_n) \in D_m$  is ingested and buffered until a batch  $X = ((\mathbf{x}_1, y_1), \dots, (\mathbf{x}_B, y_B))$  of size  $B$  has been accumulated. Then,  $X$  is preprocessed and inserted into the  $PDB_{L_m}$  as described in Algorithm 5. In words, a flow-feature vector  $\mathbf{x}$  is scaled to the range  $[-1, 1]$  by applying a feature-wise min-max normalization given by

$$\mathbf{x}' = (b - a) \frac{\mathbf{x} - \min \mathbf{x}}{\max \mathbf{x} - \min \mathbf{x}} + a \quad (4.1)$$

where  $a = -1$  and  $b = 1$ . After that, the scaled data point  $\mathbf{x}'$  is subject to both a locality-sensitive hashing function  $h$  and a non-cryptographic hashing function  $g$ . In this particular architecture,  $h$  is a GRP with a global seed for the initialization of the projection plane  $\mathbf{M}$  (see Section 2.2.3), such that regions  $r = h(\mathbf{x}')$  across local infrastructures are comparable and consistent.<sup>1</sup> Since the data is organized in regions, a nested scheme is applied for the insertion of pairs of datapoints and labels as depicted in Figure 4.4.

<sup>1</sup>Here, the words hash value and region are used synonymously

Figure 4.4: Nested indexing in a local pattern database.

In fact, the pairs within a region are further partitioned into disjoint subsets according to the true class label  $y$ . This means that for each subset of the data of a particular label within a region, a separate hashtable is initialized and inserted into the  $PDB_{L_m}$  as a second level. Thus, for the persistence of a pair  $(\mathbf{x}', y)$ , two keys  $\alpha, \beta$  are constructed (see Lines 6-7 in Algorithm 5). The key  $\alpha$  is a concatenation of the prefix constant  $p_x$ , the bit-string  $r$  and the label  $y$ . This way, the data is partitioned primarily by its region and secondarily by its label as described above. The key  $\beta$  is the result of the non-cryptographic hashing function  $g(\mathbf{x}')$ , which serves as a mechanism for deduplicating identical  $\mathbf{x}'$ . Additionally, a third key  $\gamma$  is constructed by concatenating the prefix constant  $p_y$  and the bit-string  $r$ . As it is important to retrieve all existing labels within a region efficiently in a processing step of the subsequent service,  $\gamma$  is used for storing the set of labels within a region as auxiliary metadata. Next, if not already present, a hash table is initialized and inserted into  $PDB_{L_m}$  using  $\alpha$ . Likewise, if  $PDB_{L_m}$  at slot  $\gamma$  is empty, a new set<sup>2</sup> is initialized and inserted. After that, it is checked if the slot  $\beta$  of the hash table placed at  $\alpha$  in  $PDB_{L_m}$ , is empty. In the positive case, the pair  $(\mathbf{x}', y)$  is inserted into that slot and the region  $r$  is inserted into the set  $\mathcal{R}$ . Otherwise, no data is inserted into the local pattern database and no region is added to  $\mathcal{R}$ . After processing a batch, the set of updated regions  $\mathcal{R}$  is emitted as events into  $C_{L_m}$ .

**Input:** Batch  $X$

**Output:** Regions  $\mathcal{R}$

```

1:  $\mathcal{R} \leftarrow$  new Set
2:  $\min \mathbf{x}, \max \mathbf{x} \leftarrow$  extract feature ranges from  $X$ 
3: for each  $(\mathbf{x}, y)$  in a batch do
4:    $\mathbf{x}' \leftarrow \text{normalize}(\mathbf{x})$  ► see Equation 4.1
5:    $r \leftarrow h(\mathbf{x}')$ 
6:    $\alpha \leftarrow \text{concatenate}(p_x, r, y)$ 
7:    $\beta \leftarrow g(\mathbf{x}')$ 
8:    $\gamma \leftarrow \text{concatenate}(p_y, r)$ 
9:   if  $PDB_{L_m}[\alpha]$  is None then
10:     $PDB_{L_m}[\alpha] \leftarrow$  new hash table  $H$ 
11:   if  $PDB_{L_m}[\gamma]$  is None then
12:     $PDB_{L_m}[\gamma] \leftarrow$  new set  $\mathcal{S}_r$ 
13:   if  $PDB_{L_m}[\alpha][\beta]$  is None then
14:     $PDB_{L_m}[\alpha][\beta] \leftarrow (\mathbf{x}', y)$ 
15:   insert  $y$  into the set at  $PDB_{L_m}[\gamma]$ 
16:   insert  $r$  into  $\mathcal{R}$ 
17: return  $\mathcal{R}$ 

```

Algorithm 5: Preprocessing and inserting  $B \subset D_m$  into  $PDB_{L_m}$ 

<sup>2</sup>A set is a data structure describing an unordered collection with no duplicate elements.

### 4.3.2 Complexity Estimation

As described in Section 4.1.4, a region is said to be complex if it contains more than one unique label. Otherwise, a region is simple. Since the data within a region already represents a cluster created by a locality-sensitive hashing function  $h$ , the existence of multiple classes within a single region indicates a non-linear decision boundary. On that basis we differentiate how a region is processed in the subsequent services of the pipeline. Furthermore, the complexity state of a region may vary, depending on the scope it is observed. Note that since the projection matrix  $\mathbf{M}$  that is used to construct  $h$  is initialized with the same values in every  $L_m$ , all hashes that were computed by  $h$  are globally comparable. This means that similar data points from different datasets, e.g.,  $\mathbf{x}_i \in D_1$  and  $\mathbf{x}_j \in D_2$ ,  $\mathbf{x}_i \sim \mathbf{x}_j$  may be hashed to the same region  $h(\mathbf{x}_i) = h(\mathbf{x}_j)$ . However, it is also possible that the corresponding labels  $y_i \in D_1$  and  $y_j \in D_2$  are not equal. Thus, a certain region may contain only a single unique label in both local scopes but multiple unique labels in the global scope and therefore lead to a different global view on that region's complexity state. Given that, the complexity estimation service acts as a bridge between the local and global components and answers the question, which regions are considered to be complex in a global scope.

First, a set of incoming regions  $\mathcal{R}_{\text{in}}$  is received on the  $C_{L_m}$ . Then, for each region  $r \in \mathcal{R}_{\text{in}}$  the following operations are executed (see Algorithm 6). The set of unique labels  $\mathcal{S}_r$  for a particular region within a local scope has been stored in Algorithm 5 as auxiliary metadata, which is now retrieved from the  $PDB_{L_m}$  by constructing the corresponding key  $\gamma$ . In the next step,  $\mathcal{S}_r$  has to be stored in the  $PDB_G$ . Therefore, another key  $\delta$  is constructed by concatenating the prefix constant  $p_y$ , the region  $r$  and the current local infrastructure identifier  $m$ , which prevents the collision of information from different infrastructures. After  $\mathcal{S}_r$  is stored on a global level at  $PDB_G[\delta]$ , the label set information for that region from all members in the CIDS is aggregated. That aggregated view is essentially the global complexity state for that region. By iterating over all member identifiers in the CIDS, multiple keys  $\delta$  are constructed. Each key retrieves the specific label set  $\mathcal{S}_r$  of a member and inserts its content into the temporary set  $\mathcal{S}_t$ , collecting the local label sets.

Figure 4.5: Illustration of the complexity estimation algorithm with two local infrastructures. Each local label set at  $PDB_{L_m}[\kappa]$  is synchronized into the global pattern database at  $PDB_G[\delta]$ , where  $\delta$  is constructed with  $m$ . Per region, the union operation is applied on the global label sets, whereupon the complexity is derived from.

After collecting all label sets in  $\mathcal{S}_t$ , the complexity state is obtained by simply evaluating the cardinality  $|\mathcal{S}_t|$ . If there is more than one class in a region on a global scope, that is  $|\mathcal{S}| > 1$ , then assign a true value to the global complexity variable  $c_r$ . Otherwise, assign a false value. In order to store  $c_r$ , the key  $\kappa$  is created by concatenating the prefix constant  $p_c$  and the region  $r$ . Note, that  $PDB_G[\kappa]$  is only updated, if storing  $c_r$  changes the state that is already persisted. This is because, if an update is executed, this information has to be propagated to the next service. Thus, in that case, the region  $r$  is inserted into  $\mathcal{R}_{out}$ , which is subsequently sent into the global event channel  $C_G$  in order to inform services in all local infrastructures about the update.

**Input:** Regions  $\mathcal{R}_{in}$

**Output:** Regions  $\mathcal{R}_{out}$

```

1:  $\mathcal{R}_{out} \leftarrow$  new Set
2:  $m \leftarrow \text{getID}()$  ► current local infrastructure identifier
3: for each  $r$  in  $\mathcal{R}$  do
4:    $\gamma \leftarrow \text{concatenate}(p_y, r)$ 
5:    $\mathcal{S}_r \leftarrow PDB_{L_m}[\gamma]$ 
6:    $\delta \leftarrow \text{concatenate}(p_y, r, m)$ 
7:    $PDB_G[\delta] \leftarrow \mathcal{S}_r$ 
8:    $\mathcal{S}_t \leftarrow \emptyset$ 
9:   for each  $m$  in  $\{1, \dots, M\}$  do
10:     $\delta \leftarrow \text{concatenate}(p_y, r, m)$ 
11:     $\mathcal{S}_t \leftarrow \mathcal{S}_t \cup PDB_G[\delta]$ 
12:   if  $|\mathcal{S}_t| > 1$  then
13:      $c_r \leftarrow 1$ 
14:   else
15:      $c_r \leftarrow 0$ 
16:    $\kappa \leftarrow \text{concatenate}(p_c, r)$ 
17:   if  $PDB_G[\kappa] \neq c_r$  then
18:      $PDB_G[\kappa] \leftarrow c_r$ 
19:     add  $r$  to  $\mathcal{R}_{out}$ 
20: return  $\mathcal{R}_{out}$ 

```

Algorithm 6: Construction of a global complexity state

### 4.3.3 Generative Fitting

The generative fitting service is the most demanding procedure in the context of processing resources. The service represents the filtering and compression operations presented in Section 4.1. There are two scenarios based on the region's complexity. If the region is not complex, no further actions are taken except it formally was complex. Then, existing models have to be deleted, since they are not longer used. And if the region is complex, generative models are provided, which represent the medium for exchanging information on attacks. More specifically, multiple GMM are fitted on each label-subset of a region's data, which was stored in the indexing step in Section 4.3.1. According to a model selection process that evaluates the efficacy of each GMM, the best model is stored in the global pattern database, accessible to every member in the CIDS to sample synthetic data from.

This way, every member has access to the global knowledge from all local infrastructures in order to enhance the local dataset that is used for fitting a classifier. Thus, this service is the key for providing *privacy* and *minimal overhead* while exchanging information. Considering the length and complexity of the complete algorithm, the main procedure is outlined first in Algorithm 7 and then the details on important sub-routines are elaborated subsequently.

Regions that have been updated in the preceding service are received as events  $r \in \mathcal{R}_{\text{in}}$ . Since the data is further organized per label within a region, the label set for a region  $\mathcal{S}_r$  is retrieved. Additionally, the complexity state of the region  $c_r$  is checked. Then, if the region is not complex, no model fitting is executed. Instead, potentially existing models are deleted from storage. This is the case, if the complexity status of the region has been changed from complex to simple. But if the region is currently complex, the generative model fitting procedure is triggered where new models are created and already existing models are updated. For that, from every hash table within a region, the original flow samples are extracted and collected in  $\mathcal{X}_\alpha$ , which is then stored in  $T$  with the corresponding label as the key. The goal is to fit a model on each  $\mathcal{X}_\alpha$  within a region, such that the collection of models for a region can be used in combination for sampling the synthetic data. Note that this is a specific process for the employed generative algorithm. Since GMMs cannot be conditioned on multiple labels.

**Input:** Regions  $\mathcal{R}_{\text{in}}$

**Output:** Regions  $\mathcal{R}_{\text{out}}$

```

1:  $\mathcal{R}_{\text{out}} \leftarrow \emptyset$ 
2: for each  $r$  in  $\mathcal{R}_{\text{in}}$  do
3:    $\kappa \leftarrow \text{concatenate}(p_c, r)$ 
4:    $\delta \leftarrow \text{concatenate}(p_y, r, m)$ 
5:    $c_r \leftarrow PDB_G[\kappa]$ 
6:    $\mathcal{S}_r \leftarrow PDB_G[\delta]$ 
7:   if  $c_r = 0$  then
8:     for each  $y$  in  $\mathcal{S}_r$  do
9:        $\omega \leftarrow \text{concatenate}(p_d, r, y, m)$ 
10:      delete model in  $PDB_G[\omega]$ 
11:   else
12:      $T \leftarrow \text{new hash table}$ 
13:     for each  $y$  in  $\mathcal{S}_r$  do
14:        $\alpha \leftarrow \text{concatenate}(p_x, r, y)$ 
15:        $\mathcal{X}_\alpha \leftarrow \text{extract values (flows) from } PDB_{L_m}[\alpha]$ 
16:        $T[y] \leftarrow \mathcal{X}_\alpha$ 
17:      $T \leftarrow \text{upsampling}(T)$ 
18:     for each  $(y, F_y)$  in  $T_F$  do
19:        $\text{GMM} \leftarrow \text{modelSelection}(y, F_y)$ 
20:        $\omega \leftarrow \text{concatenate}(p_d, r, y, m)$ 
21:        $PDB_G[\omega] \leftarrow \text{GMM}$ 
22:   add  $r$  to  $\mathcal{R}_{\text{out}}$ 
23: return  $\mathcal{R}_{\text{out}}$ 

```

Algorithm 7: Generative Fitting (Main Procedure)

Note that this is a specific process for the employed generative algorithm. Since GMMs cannot be conditioned on multiple labels, multiple single label models have to be fitted. Subsequently, upsampling operations prepare the collected region data in  $T$  for the model fitting (see Algorithm 8). After that, the model selection process is started sequentially for each available label in the region (see Algorithm 9). Finally, the best fitted model is stored in the  $PDB_G$ .

So far, the main procedure has been outlined. Next, the details on the upsampling are elaborated (see Algorithm 8). As each  $\mathcal{X}_\alpha$  is used for the fitting of a GMM and since some of these flow data subsets of a region potentially exhibit a low number of samples, an upsampling process may need to be applied. The upsampling process ensures that the fitting algorithm for the GMM is able to work. For that, the number of samples has to be at least equal to the number of components of the GMM which in turn is at most equal to the number of dimensions of the training dataset  $\mathcal{X}_\alpha$ . And since different parameters for the number of components are tried during the model selection, the upper limit for the parameter is used as a comparison value. In this case the upper limit for the number of components is the number of dimensions of the training data. If this is not the case, the upsampling fills the lacking samples artificially.

For the initialization of the responsibilities of the mixture components within the fitting procedure of the GMM the k-means algorithm is used to find distinct clusters within  $\mathcal{X}_\alpha$ . The resulting cluster assignments for each  $\mathbf{x} \in \mathcal{X}_\alpha$  are then used as initial values for the responsibilities. A supersampling process results in duplicate points that could lead to a smaller number of distinct clusters found by the k-means algorithm than the number of components specified in the model. Therefore, the upsampling is realized by generating near neighbours per sample.

First, the number of neighbours to generate per sample  $N_\Delta$  is determined by dividing the difference of the dimensionality of the flow data  $\dim(\mathcal{X}_\alpha)$  and the number of data points  $|\mathcal{X}_\alpha|$  by  $|\mathcal{X}_\alpha|$  using an integer division. This ensures that each original data point  $\mathbf{x}$  contributes an equal share to the total amount of newly sampled points  $\hat{\mathbf{x}}$ . In case, the result of the integer division is zero, one is added to the result. Then for each data point  $\mathbf{x} = [x_1, \dots, x_D]^\top$ , nearest neighbours are generated by sampling from a uniform distribution  $\mathcal{U}(a, b)$ .

**Input:** Hash table  $T$  with labels  $y$  as keys and sets of flows  $\mathcal{X}$  as values

**Output:** Hash table  $T$  with upsampled sets of flows

```

1: for each  $(y, \mathcal{X}_\alpha)$  in  $T$  do
2:   if  $y \neq 0$  and  $|\mathcal{X}_\alpha| < \dim(\mathcal{X}_\alpha)$  then
3:      $\hat{\mathcal{X}} \leftarrow \emptyset$ 
4:      $N_\Delta \leftarrow \lfloor \dim(\mathcal{X}_\alpha) - |\mathcal{X}_\alpha| / |\mathcal{X}_\alpha| \rfloor + 1$ 
5:     for each  $\mathbf{x}$  in  $\mathcal{X}_\alpha$  do
6:       for each  $n$  in  $\{1 \leq n \leq N_\Delta\}$  do
7:          $\hat{\mathbf{x}} \leftarrow [s(x_1), \dots, s(x_D)]^\top$  with  $s(x_d) \sim \mathcal{U}(a, b)$ 
8:         add  $\hat{\mathbf{x}}$  to  $\hat{\mathcal{X}}$ 
9:      $\mathcal{X}_\alpha \leftarrow \mathcal{X}_\alpha \cup \hat{\mathcal{X}}$ 
10:     $T[y] \leftarrow T[y] \cup \mathcal{X}_\alpha$ 
11: return  $T$ 

```

Algorithm 8: Binary Splitting and Upsampling of Region Data

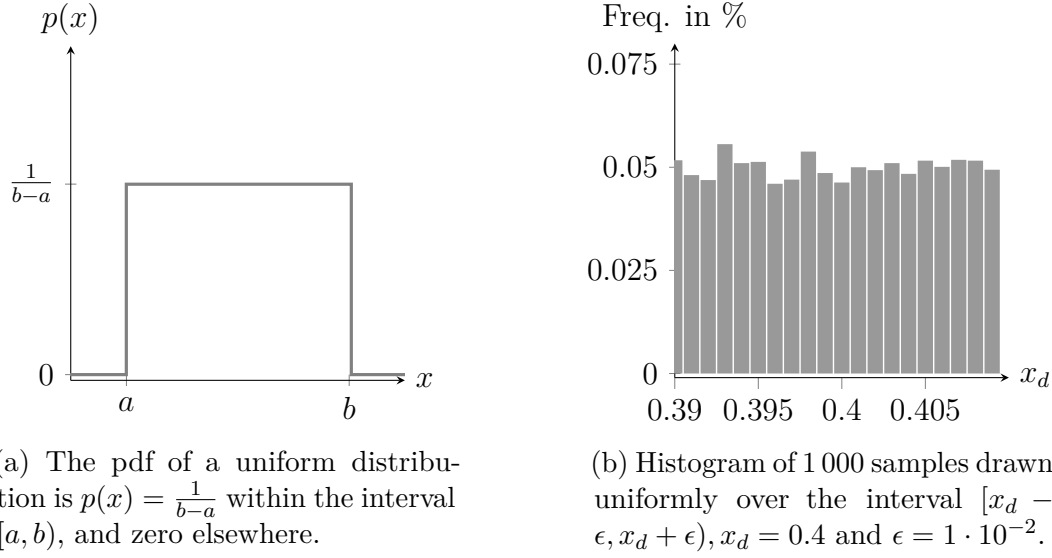

Figure 4.6: Nearest neighbours are generated by sampling each feature value from a the uniform distribution.

That way, the nearest neighbour of  $\mathbf{x}$  is the concatenation of the sampled feature values as  $\hat{\mathbf{x}} = [s(x_1), \dots, s(x_D)]^\top$ , where  $s(x_d) \sim \mathcal{U}(a, b)$  is defined as the value sampled from the uniform distribution within the interval  $[x_d - \epsilon, x_d + \epsilon)$ . The value  $\epsilon$  controls the size of the interval of the uniform distribution. The larger the value for  $\epsilon$ , the further the newly generated values deviate from the original feature values. In Figure 4.6b the value for a single feature  $x_d$  is drawn uniformly at random. The original value of the feature was  $x_d = 4$ , which was extended by  $\epsilon = 1 \cdot 10^{-2}$ . By choosing a relatively small value for  $\epsilon$ , it is ensured that the generated nearest neighbours do not alter the original data distribution significantly, while enabling a more ideal fitting of the GMM for that set of data points. Finally, the generated neighbours and the original data points are combined. After processing each pair  $(y, \mathcal{X}_\alpha)$ , the hash table  $T$  is returned to the main procedure (Algorithm 7) for the subsequent model selection.

In the next phase of the algorithm, one GMM is selected per unique label within a region. During the selection process multiple models are fitted with different model parameters using a flow data subset  $\mathcal{X}_\alpha$ . Since the resource demands of the EM Algorithm for fitting a GMM are relatively high, the dimensionality of the training data is reduced by applying a dimensionality reduction via PCA. Later in the pipeline, when sampling data from the GMMs, the inverse operation of the corresponding PCA is applied on the synthetic data in order to restore the original feature space. Therefore, the parameters of the PCA have to be stored in the  $PDB_G$  along with the parameters of the GMM.

Note, that during the application of PCA in the first place, information within the data is lost by only keeping the components that describe most of the variance of the data. Of course, the result of the inverse transformation would then only be an approximation of the original data. However, the input for the inverse transformation is going to be the synthetic data. Thus, we accept the loss and focus on the fact that the synthetic data is transformed back into the original feature space, such that the synthetic data resembles more the original data as it was captured, increasing its compatibility.

The model selection is specified in Algorithm 9. First PCA is applied on  $\mathcal{X}_\alpha$  resulting in

a set of flows  $\mathcal{X}'_\alpha$  with a reduced feature set. The number of components of the PCA has to be set heuristically or a threshold has to be set, which defines the minimum amount of variance that needs to be explained by a specific number of components. After the compression, the parameter search for the GMM is started. In general, there is no exact method to determine the optimal parameters for a GMM, such that different parameter settings have to be evaluated. For that, the search space is defined by two dimensions, namely the number of components and the type of covariance matrix that is used for each component. The set of numbers that is used for specifying the number of components is referred to as  $\mathcal{K}$ . The covariance matrix can either be a standard covariance matrix with a full set of entries or can be an approximation with entries only on the diagonal of the matrix, i.e., we define  $\mathcal{C} = \{\text{"full"}, \text{"diagonal"}\}$ . The reason behind the choice of both types of covariance matrix is also motivated by heuristical optimization. The full covariance matrix can result in overfitting, especially on small datasets, whereas the diagonal matrix acts as a type of regularization to the model. However, depending on the data the diagonal type sometimes also leads to an underfitting of the model.

After fitting a GMM on  $\mathcal{X}'_1$  the first metric for the selection is calculated. Precisely, the BIC is calculated as in Equation 2.20 (see Section 2.3.3). Note, that for the case of a diagonal covariance matrix, the number of entries of the covariance matrix to estimate changes from  $\frac{D(D+1)}{2}$  to  $D$ . Thus, given a GMM with  $K$  mixture components, each exhibiting a diagonal covariance matrix, and a dataset  $\mathcal{X}_1$  consisting of  $N$  data points and  $D$  features, the BIC is defined as

$$\text{BIC}(\text{GMM}|\mathcal{X}_1) = (KD + D + K - 1) \ln(N) - 2 \ln(\hat{L}). \quad (4.2)$$

After that, a second evaluation metric is calculated (see Algorithm 10). The process that is used to gather that metric is called adversary evaluation and is based on the principles of Generative Adversarial Networks (GANs).

**Input:** Dataset  $\mathcal{X}_1$

**Output:** Tuple ( $GMS$ , GMM, PCA)

- 1:  $\mathcal{X}'_1 \leftarrow \text{PCA}(\mathcal{X}_1)$
- 2:  $\mathcal{K} \leftarrow \{4k \mid k \in \mathbb{N}, 1 \leq k \leq \dim(\mathcal{X}_1)\}$
- 3:  $\mathcal{C} \leftarrow \{\text{"full"}, \text{"diagonal"}\}$
- 4:  $L \leftarrow \text{new list}$
- 5: **for each**  $k$  in  $\mathcal{K}$  **do**
- 6:   **for each**  $c$  in  $\mathcal{C}$  **do**
- 7:      $\text{GMM} \leftarrow \text{fitGaussianMixture}(\mathcal{X}'_1, k, c)$
- 8:      $\text{BIC} \leftarrow \text{BIC}(\text{GMM}, \mathcal{X}'_1)$
- 9:      $\text{ACC} \leftarrow \text{AdversaryEvaluation}(\mathcal{X}_1, \text{GMM}, \text{PCA})$
- 10:     $GMS \leftarrow \text{GMS}(\text{BIC}, \text{ACC})$
- 11:    add ( $GMS$ , GMM, PCA) to  $L$
- 12: sort  $L$  according to the values of  $GMS$
- 13: **return** ( $GMS$ , GMM, PCA) with the lowest value for  $GMS$

Algorithm 9: Model Selection

Fitting a Generative Adversarial Network (GAN) involves a discriminator function, i.e., classifier that tries to distinguish between the original and synthetic data. In other

(a) A poor fitted generative model: The original data (triangles) and the synthetic data (circles) can be easily separated by a classifier.

(b) A well fitted generative model: The synthetic data resemble the original data well, such that a separation is not easy.

Figure 4.7: Adversary evaluation: separate original and fake data.

words, the generative algorithm synthesizes fake data, which resembles the original data. Based on that, a dataset is assembled by combining fake data labeled as the positive class (1) and original data labeled as the negative class (0) or vice versa. This dataset is shuffled and split into a training and test proportion.

Then, a discriminative model is trained on the training proportion, trying to find distinguishing features within both classes, allowing a distinction to be made. Within the evaluation step, the discriminator is tested on its ability to separate fake and original data. The lower the score of the discriminator, the better the generative model. Figure 4.7 illustrates two scenarios. In the first scenario (a), the generative model has been fitted poorly, because the synthetic data can be easily separated from the original data as indicated by the decision boundary (dashed line). In the second scenario (a), the generative model performs well by creating synthetic data that could not be separated from the original data.

**Input:**  $\mathcal{X}_1$ , GMM, PCA

**Output:**  $ACC$  from decision tree model  $DT$

- 1:  $\tilde{\mathcal{X}}'_1 \leftarrow \text{sample } |\mathcal{X}_1| \text{ data points from GMM}$
- 2:  $\tilde{\mathcal{X}}_1 \leftarrow \text{PCA}^{-1}(\tilde{\mathcal{X}}'_1)$
- 3:  $\mathcal{Y} \leftarrow \{1\}$
- 4:  $\tilde{\mathcal{Y}} \leftarrow \{0\}$
- 5:  $\mathcal{D} \leftarrow \text{concatenate}(\mathcal{X}_1 \times \mathcal{Y}, \tilde{\mathcal{X}}_1 \times \tilde{\mathcal{Y}})$
- 6:  $\mathcal{D}_{\text{train}}, \mathcal{D}_{\text{test}} \leftarrow \text{shuffleSplit}(\mathcal{D})$
- 7:  $DT \leftarrow \text{fitDecisionTree}(\mathcal{D}_{\text{train}})$
- 8:  $\hat{\mathcal{Y}} \leftarrow \text{predict } \mathcal{X}_{\text{test}} \subset \mathcal{D}_{\text{test}} \text{ with } DT$
- 9:  $ACC \leftarrow ACC(\mathcal{Y}_{\text{test}}, \hat{\mathcal{Y}})$
- 10: **return**  $ACC$

Algorithm 10: Adversary Evaluation

In order to quantify the performance of the discriminator within the adversary evaluation, a classification metric is calculated. Since the original and synthetic data is equal

in size and the posed problem is binary the accuracy score ( $ACC$ ) is chosen, which is defined as

$$ACC = \frac{TP + TN}{TP + TN + FP + FN} \quad (4.3)$$

For each iteration in the model selection process, both the BIC and the  $ACC$  are stored. After all parameter combinations have been exhausted and all resulting models have been evaluated a combined metric that we call generative model selection ( $GMS$ ) is calculated from the BIC and  $ACC$  for each model. For that, the value range of both metrics must be aligned, such that the BIC is normalized into the range  $[0, 1]$  by applying the min-max-normalization from Equation 4.1. After that, the mean is calculated for each metric pair as defined in Equation 4.4. Finally, the model with the lowest combined  $GMS$  is selected.

$$GMS = \frac{1 - ACC + BIC}{2}. \quad (4.4)$$

The model parameters of both the GMM and the PCA are stored in the  $PDB_G$ . In numbers, these can range, depending on which type of covariance matrix is chosen for the GMM. PCA on the other hand, requires a  $D \times M$  projection matrix, with  $D$  being the dimensions of the original data space and  $M$  being the number of dimensions in the projected subspace. Note that  $|\mathcal{S}_y|$  defines the number of unique labels within a region, which effectively determines the number of model pairs (GMM, PCA) that are to be stored per region. Therefore, per region, the number of parameters to store is at least

$$|\mathcal{S}_y| (2KD + K - 1 + MD)$$

and at most

$$|\mathcal{S}_y| \left( (KD + K \frac{D(D+1)}{2} + K - 1) + MD \right).$$

#### 4.3.4 Classifier Fitting

The objective of the classifier fitting service is to provide the local infrastructures with the latest synthetic dataset for enhancing a local model fitting. Two different functional modes can be distinguished. First, as already described, a synthetic dataset is provided and the model that results from the respective fitting is used as the only detection algorithm. In addition to that, it is also possible to perform classifications directly with locality sensitive hashes from the pattern database. Thus, alongside the classifier model from the first scenario, a second detection algorithm based on LSH may be utilized in parallel. Therefore, in this section we first describe how to create a synthetic dataset using generative models. Subsequently, the classification with the help of the hashes is explained and formalized.

The goal is to ensure that changes to the  $PDB_G$  are disseminated to the local infrastructures as quickly as possible. Thus, after each change to the generative models in the  $PDB_G$  made by the previous service, an event is sent into all local communication

channels. The classifier fitting service, that is executed locally within each infrastructure, receives these events within a defined time window and collects them. Upon the termination of the time window the classifier fitting service is initiated and begins with assembling a training dataset, if at least a single event was collected. All generative models are loaded sequentially from the  $PDB_G$  and synthetic data is generated in the amount that was also originally found in the corresponding region by sampling from the respective GMMs. After that, the synthetic data is transformed from the lower-dimensional subspace to the original data space by the inverse function of the original PCA operation using the stored parameters. In order to fit a classifier, the local training dataset is loaded from the respective  $PDB_L$  and blended with the synthetic data. Subsequently, the inverse normalization operation is also applied on both the original and the synthetic data by loading the corresponding parameters that were used to normalize the data before indexing it. Finally, the first scenario consists of using the fitted classifier for detection.

For the second scenario, we describe how to perform hybrid attack detection using the classifier from the first scenario and the pattern detector in combination. First, incoming flows are normalized and hashed using a GRP with the same parameters that were used for indexing the data into the  $PDB$ . Using the resulting hash  $r$ , the corresponding region complexity state is retrieved. If the result from the lookup is empty, that means that no such region exists in the  $PDB$ . In that case, the flow is classified using the model  $M$  that was fitted on both synthetic and real train data. Similarly, if a region complexity state is found to be complex, the flow is classified using  $M$  as well. If it turns out that the flow is assigned to a simple region, the corresponding label is loaded from the  $PDB$  and used as the classification result.

**Input:** Stream of incoming flows  $\mathbf{X}$

**Output:** List of predictions  $\hat{Y}$

```

1:  $\hat{Y} \leftarrow$  new List
2: for each  $x$  in  $\mathbf{X}$  do
3:    $x' \leftarrow \text{normalize}(x)$  ► see Equation 4.1
4:    $r \leftarrow h(x')$  ► see Equation 2.7
5:    $c_r \leftarrow PDB_G[\kappa]$  ► see Algorithm 6
6:   if  $c_r \neq \emptyset$  then
7:     if  $c_r = 0$  then
8:        $\mathcal{S}_r \leftarrow PDB_G[\delta]$  ► see Algorithm 6
9:        $\hat{y} \leftarrow \mathcal{S}_r$ 
10:    else
11:       $\hat{y} \leftarrow$  predict  $x$  with classifier model  $M$ 
12:    else
13:       $\hat{y} \leftarrow$  predict  $x$  with classifier model  $M$ 
14:    append  $\hat{y}$  to  $\hat{Y}$ 
15: return  $\hat{Y}$ 

```

## Chapter 5

# Experimental Evaluation

## 5.1 Network Flow Data

First the employed datasets and the included attacks are presented shortly at the beginning in Section 5.1.1. After that, the feature extraction process is described in Section 5.1.2. There, it is described which flow exporter is used for the feature extraction and which features are obtained during the extraction. Section 5.1.3 present the preprocessing steps for the datasets, which include the labeling and data selection. For transparency, the distribution of different classes within each dataset is elaborated. A combined analysis of the feature importances for all datasets shows that no further feature selection would be beneficial, which finalizes the data description.

### 5.1.1 Employed Datasets

From the evaluation perspective, the employed datasets should both reflect similarities and diversity regarding the contained traffic in order to enable a realistic evaluation of the features of the PDB. Therefore, multiple IT-infrastructures that are members of the CIDS are simulated by incorporating different benchmark datasets. The three following datasets are selected, which are from now on referred to by the corresponding roman numeral:

- I CSE-CIC-IDS2018 [Com18],
- II CIC-IDS2017 [SHG18],
- III CIC-DoS2017 [Jaz+17].

The most important criterion for the selection was, as already described at the beginning, the assurance of a non-exclusive existence of common classes among the datasets. Both dataset I and II are very alike from the included scenarios and attacks as they are designed as a diverse and comprehensive benchmark dataset originating from a common source. Nonetheless, they differ greatly with respect to the utilized testbed. Dataset II consists of an attack network with four workstations and a victim network with three servers and ten workstations. In contrast to that, for the creation of dataset I an attack network consisting of 50 workstations and a victim network consisting of 420 workstations and 30 servers were employed. Dataset III is an intrusion detection dataset that contains besides the benign traffic only traces of application layer DoS attacks. This dataset differentiates from the others from the perspective of diversity with regard to the tools that were employed for the execution of the DoS attacks. However, a variety with regard to different attacks only exists for Dataset I and II. These attacks and, if relevant, how they are carried out are summarized below.

The botnet scenario describes compromising systems so that they can be controlled as so-called bots by Command and Control (C&C) software. Subsequently, there are a number of different ways to abuse the system, such as installing backdoors, collecting and sending sensitive data, or using the computing resources to carry out a DoS attack. Two different trojan horse malware packages, namely Zeus<sup>1</sup> and Ares<sup>2</sup>, are used for creating the botnet traffic. Zeus was employed for the traces of dataset I, whereas Ares was used for both dataset I and II.

---

<sup>1</sup>[https://github.com/ruCyberPoison/Zeus-Zbot\\_Botnet](https://github.com/ruCyberPoison/Zeus-Zbot_Botnet)

<sup>2</sup><https://github.com/sweetsoftware/Ares>

The bruteforce scenarios include attacking logins via File Transfer Protocol (FTP), Secure Shell Protocol (SSH) and Hypertext Transfer Protocol (HTTP) by using the Patator<sup>3</sup> tool. In particular, a dictionary attack is executed. It is not known whether the login usernames are already known in advance. In all three datasets, DoS and Distributed Denial of Service (DDoS) scenarios were executed. The executed DoS attacks can be categorized into so-called high-volume and low-volume [Cam+13] attacks based on HTTP. A DDoS attack has the same objective as a DoS attack, but its effectiveness is increased by using multiple compromised computer systems as the source of the attack. The DDoS traces of dataset I include attacks generated by High Orbit Ion Cannon (HOIC) and Low Orbit Ion Cannon (LOIC), whereas in the case for dataset II only LOIC was employed. HOIC targets the application layer by sending HTTP requests. LOIC is capable of generating Transmission Control Protocol (TCP) and User Datagram Protocol (UDP) as well as HTTP traffic. By deploying the Damn Vulnerable Web App (DVWA) on victim systems, web attacks such as SQL-Injection and Cross-Site Scripting (XSS) were executed against that application. The DVWA is a web application that is designed to be attacked for, e.g. educational purposes. Furthermore, the Heartbleed<sup>4</sup> exploit was executed on a server system. First, a vulnerable version of OpenSSL was compiled on the server. Subsequently, the server's memory was retrieved with the help of the Heartleech tool. Heartbleed is an exploit in the OpenSSL cryptography library. By sending a malformed heartbeat request to the respective receiver, the sender can read protected memory areas of the victim system. This allows, for example, to read encrypted communication or steal secret keys. Both dataset I and II contain portscan traffic generated by using a port scanner. A port scanner is software that can be used to check which services a system offers and on which ports they can be accessed. Furthermore, datasets I and II each contain so-called infiltration scenarios. These scenarios reflect complex attack strategies aimed at infiltrating the victim network from the inside. In both examples, a malicious Portable Document Format (PDF) file is sent to the victim system. Upon the usage of the file within a document reader, a vulnerability of the reader application is exploited. After the successful exploitation, a backdoor is executed on the victim system. Finally, the victim system is used for reconnaissance activities within the victim network.

The variety of different attacks present in the datasets are shown in Table 5.3 for reference. It can be seen that there is quite an extensive variety in the data. Furthermore, there are both large similarities and overlaps between the datasets in terms of attack types as well as large differences in terms of the testbed employed. Overall, the variance in the data is considered to be relatively large, providing a realistic representation of the spectrum of traffic that is expected from participants within the CIDS.

### 5.1.2 Feature Extraction

Within the context of real time flow feature analysis it is often neglected that flows are exported upon termination of the corresponding communication, which is either triggered by an activity or inactivity timeout mechanism. The specific setting of the timeout values is often a tradeoff between low data volume with a high timeout setting on the one side and a fine-grained analysis with low timeout values on the other side.

Table 5.1: The number of the exported flows with the name of the respective capture files and the corresponding dataset.

However, a low detection latency heavily depends on timely available data. Thus, high timeout values lead to a considerable delay of the data that is relevant to the intrusion detection pipeline, which is not acceptable in most cases. However, reducing the timeout values increases the data volume that is to be analyzed which in turn requires the corresponding computational resources. A compromise is the utilization of sub-flows. Additionally to the timeout values, exporting a sub-flow is triggered as soon as a specified number of packets have been transferred within the communication. In this example, instead of the whole packet stream, only the first 10 packets for both directions are considered, resulting in early statistical flow features. This way, the flow data is delivered in a timely manner while reducing the data volume. The only drawback of this approach is the loss of information relevant for the intrusion detection.

A flow exporter that is implemented using the Python Framework NFStream is used for tracking and exporting bidirectional network flows. A total of 45 flow features are extracted, including the basic 5-tuple and various statistical values based on the number of packets, packet sizes, and inter-arrival times. A detailed listing of all features is presented in Table 5.2. An active and inactive timeout of 15 seconds is specified for the flow export. All datasets presented in Section 5.1.1 are available in the pcap capture file format. Files from the datasets II and III were exported directly. In the case of dataset I further preparations were required. Some files contained broken headers, which were fixed with the pcapfix repair tool. In addition, the individual days, by which the dataset is structured, were fragmented further into many individual files, which were merged into single files using the pcapmerge tool. Subsequently, these files were exported. The number of the resulting flow samples are shown in Table 5.1.

ID	Feature Description	ID	Feature Description	ID	Feature Description
1	Source IP address	16	Max. packet IATs (source → destination)	31	Median packet IATs (destination → source)
2	Source Port	17	Mean packet IATs (source → destination)	32	Std. Dev. packet IATs (destination → source)
3	Dest. IP address	18	Median packet IATs (source → destination)	33	Number packets (bidirectional)
4	Dest. Port	19	Std. Dev. packet IATs (source → destination)	34	Sum packet sizes (bidirectional)
5	Protocol	20	Number packets (destination → source)	35	Min. packet sizes (bidirectional)
6	UNIX Timestamp	21	Sum packet sizes (destination → source)	36	Max. packet sizes (bidirectional)

8	Sum packet sizes (source → destination)	23	Max. packet sizes (destination → source)	38	Median packet sizes (bidirectional)
9	Min. packet sizes (source → destination)	24	Mean packet sizes (destination → source)	39	Std. Dev. packet sizes (bidirectional)
10	Max. packet sizes (source → destination)	25	Median packet sizes (destination → source)	40	Sum packet IATs (bidirectional)
11	Mean packet sizes (source → destination)	26	Std. Dev. packet sizes (destination → source)	41	Min. packet IATs (bidirectional)
12	Median packet sizes (source → destination)	27	Sum packet IATs (destination → source)	42	Max. packet IATs (bidirectional)
13	Std. Dev. packet sizes (source → destination)	28	Min. packet IATs (destination → source)	43	Mean packet IATs (bidirectional)
14	Sum packet IATs (source → destination)	29	Max. packet IATs (destination → source)	44	Median packet IATs (bidirectional)
15	Min. packet IATs (source → destination)	30	Mean packet IATs (destination → source)	45	Std. Dev. packet IATs (bidirectional)

Table 5.2: Flow features are extracted from the network traffic, including the 5-tuple, timestamp and statistical early flow features

Although the datasets have common attack classes, they are strongly imbalanced regarding the number of samples per class. This mainly results from the differences in the architectures of the employed testbeds, where the traces were recorded in.

### 5.1.3 Preprocessing

The exported flow samples are labeled based on domain knowledge, such as timestamps and IP addresses, that is available on the respective website from which the datasets can be accessed. Improvements of the labeling process regarding corrected timestamps and further sanity checks, which are described in [ERJ21], have been taken into account. For example, traces that were produced by the DoS Hulk tool are neglected, because the tool is not implemented well and does not produce any meaningful attack data. Table 5.3 shows the number of samples per class of each respective dataset. Specific attack samples that are either not meaningful (DoS Hulk) or only represented in a single dataset (Brute-Force-FTP) or are too specific to be evaluated on (Infiltration) are removed, which is indicated by a grey cell color in the table.

For the chosen evaluation strategy, the dataset is further preprocessed by restructuring related attack samples and grouping them into a common class. For example, all samples that represent a low volume DoS attack that were produced by one of the many tools are grouped into a single class called “DoS HTTP Low Volume”. Subsequently, the different classes receive a numeric label. The regrouping and relabeling of the attack classes across the different datasets enables a basis on which a reasonable communication within the CIDS can happen in the first place. In practice, this approach would correspond to a centrally controlled policy that tells the individual members how their local datasets must be labeled before inserting them into the pattern database. The resulting classes and corresponding sample counts are shown in Figure 5.3. The already mentioned class imbalances across the datasets are not further addressed in the preprocessing steps as this subject is handled in the Classifier Fitting Service (see Section 4.3.4).

In the next step, the data is analyzed regarding the feature importances. From these results, it can be derived, if a common feature subset across all datasets can be selected. Recall, that both the feature set and the labels must match across the different datasets in order for the CIDS to work. Feature selection can be seen as a form of dimensionality reduction. Common advantages are an improved learning performance, an increased computation efficiency, a decrease in memory and storage consumption as well as better generalization capabilities of the resulting models [Li+17]. As a method for computing the feature importance the permutation importance, also called Mean Decrease in Accuracy (MDA), is selected. The MDA is assessed for each single feature by removing the association between the feature and the target by randomly permuting the values of the feature and measuring the increase in error that results from that [Lou14, p. 125]. Algorithm 12 describes this procedure in detail.

Figure 5.1 shows the permutation importances for each dataset, with the results being scaled to  $[0, 1]$  in order to establish comparability of the values across the datasets. It can be seen that there is no common tendency for a subset of significant features that could be selected. Moreover, as this exemplary setup with only three different datasets already delivers this result, the chances are high that this trend increases with higher numbers of datasets, i.e., members in the CIDS. Thus, the complete set of extracted features is used for the information exchange within the CIDS. Intuitively that makes sense, because the initial goal was to provide a general knowledge database, which each member of the CIDS can incorporate in its detection pipeline with their individual preprocessing steps.

**Input:** Fitted model  $M$

**Output:** vector  $\mathbf{f}$  with feature importances as elements

- 1: Compute the reference score  $s$  of the model  $M$  on data  $\mathcal{X}$
- 2: **for each** feature column  $\{x_{d,1}, \dots, x_{d,N} \mid 1 \leq d \leq D\}$  **do**
- 3:   **for each** iteration  $j$  in  $1, \dots, J$  **do**
- 4:     randomly shuffle column  $d$  of dataset  $\mathcal{X}$  resulting in corrupted data  $\hat{\mathcal{X}}_{j,d}$
- 5:     compute the score  $s_{j,d}$  of model  $M$  on  $\hat{\mathcal{X}}_{j,d}$
- 6:   compute importance  $\iota_d = s - \frac{1}{K} \sum_{j=1}^K s_{j,d}$  and insert  $\iota_d$  into  $\mathbf{f}_d$
- 7: **return** feature importance vector  $\mathbf{f}$

Figure 5.1: Flow Feature Importance Analysis Using Mean Decrease Accuracy (MDA)

## 5.2 Experimental Setup

Section 5.2.1 presents details on the implementation of the application. This includes the conceptual realization of the architecture that is outlined in Section 4.2 and the technology solutions that were adopted. Furthermore, internals of the data and communication flow between individual services of the application are explained. Finally, two aspects are discussed in more detail. For one thing, the technology for parallelization and thus scaling is covered. For another, the differentiated possibilities for data consistency will be highlighted. Section 5.2.2 discusses the design of the experiments used to evaluate the advantages of the CIDS compared to isolated IDS. The focus here is on testing the improvement of the detection performance under the assumption of the existence of local knowledge gaps and the reduction of the data volume to be exchanged.

### 5.2.1 Implementation Details

A cloud-oriented architecture, consisting of four services for data processing (see Section 4.2), is realized as a python streaming application <sup>5</sup>. The data processing services, message queues and key-value stores are deployed using docker compose. Scalability, availability and resilience are achieved by deploying each service in a replicated fashion. Kafka is employed as the message queue that realizes the global and local event channels, that are responsible for distributing jobs among instances of the processing services. The global and local pattern databases are realized using Redis. As described in Section 4.1, intrusion detection datasets are partitioned into regions and stored by using the respective regions as keys. In that way, data parallelization is achieved. In particular, data from each region in the key-value store can be processed independently. Hence, regions are also exploited as a job-distribution primitive. In other words, each processing service receives regions by listening on a specific topic of a Kafka message broker. As all instances of a service belong to a common consumer group, regions in a topic are distributed among the respective instances. Upon the reception of a region, a service starts its specific processing instructions on the data partition of the respective region by loading the data from the key-value store using the region as the key.

Figure 5.2: Operation Principles of a Processing Service

<sup>5</sup><https://gitlab.informatik.hs-fulda.de/verca/pattern-database>

As the processing services effectively manage the dissemination of data between all members of the CIDS, the data consistency between infrastructures depends on the processing guarantees given by the employed message queue that distributes the jobs among the processing instances. Kafka provides a configuration that enables transactional communication, such that a strong consistency can be achieved. For example, upon the successful execution of operations on a data partition, the messaging queue can be notified and the job is done. In contrast to that, upon a failure, the messaging service will try to distribute that job again. Typically, the decision for transactional guarantees comes with the cost of a higher delay. Furthermore, for data availability and consistency on a datastore-level, the consistency guarantees of the employed data store is relevant. Redis implements a master-replica scheme with asynchronous replication and this provides an eventual consistency.

### 5.2.2 Methodologies

The evaluation of the approach focuses on two main questions. Does the CIDS improve the attack detection of local IDS in cases of local knowledge gaps and how much compression can be achieved and therefore reduce the communication overhead between local IDS in terms of data volume? In order to answer the question of attack detection improvement, extensive experiments evaluate the classification results of local IDS with and without the help of the CIDS. The compression capabilities of the approach is determined by analyzing the data within the pattern databases. The experiments are conducted using different configuration parameters for the hash size in order to reason about the partitioning effect of the Random Projection operation on the datasets and the resulting quality of the generative models.

The classification experiments are constructed to simulate the absence of knowledge within a local infrastructure. At first, the operating classifier that performs attack detection in that local infrastructure is not aware of specific attack information. However, by participating in the CIDS, the local infrastructure is provided with attack information from other infrastructures that might fill its local knowledge gap. That local knowledge gap is constructed by removing a single attack class from the training dataset. As the testing dataset stays unaltered, the classifier is confronted with samples from an attack class that do not occur within its local training dataset. Systematically, in each iteration one attack class within the training dataset is removed and a classifier is fitted and evaluated. We refer to this type of evaluation as Skip-One-Class-Evaluation (SOCE). Logically, a single SOCE includes as many iterations, i.e. experiments, as there are attack classes in the local dataset of the evaluated infrastructure (see Table 5.4).

Dataset	Attack Class								
	Brute Force		Web Attack		DoS			DDoS	Bot
	SSH	Web	SQL Inj.	XSS	HTTP High Vol.	HTTP Low Vol.			
I	✓	✓	✓	✓	✓		✓	✓	✓
II	✓	✓	✓	✓	✓		✓	✓	✓
III	✗	✗	✗	✗	✓		✓	✓	✗

Table 5.4: The table indicates whether a dataset includes a particular attack class (✓) or not (✗).

The described classification experiments are conducted in two scenarios. The first one considers to create a synthetic dataset from the generative models within the pattern database and enhance the training dataset. The second scenario additionally includes the attack information provided by simple regions in the pattern database and therefore implies the help of the classification algorithm presented in Section X. In particular, flows from the testing dataset are hashed using the same Random Projection operation that is used for managing the Pattern Database. Then, the resulting hashes are compared to the hashes stored in the Pattern Database. If a hash represents a simple region, the contained label information is used as the classification result for the respective flow. And if the hash represents a complex region or is not available in the Pattern Database, the classifier that was fitted with the enhanced dataset is used for classification.

Three different hash sizes (16-bit, 32-bit and 48-bit) are considered for all classification experiments. Additionally, two different baseline experiments are conducted for comparison. These two baseline experiments also involve the removal of single attack classes as described above. In the first experiment no data is shared between the infrastructures, which represents a scenario with isolated IDSs only. The second experiment considers to fill knowledge gaps with real data. That scenario refers to an alternative CIDS, in which the training datasets are exchanged directly without any further. That means that the training dataset is merged with the original data from the training proportions of the other datasets. The obtained results represent the maximum performance that the presented CIDS could theoretically achieve with the provided datasets. As there are three local infrastructures, two baseline scenarios and two scenarios for the presented architecture, each conducted with three different hash sizes, a number of 190 experiments are executed for the evaluation.

The same classification algorithm (Random Forest) and test size (25%) is used for each experiment. Regarding the classification algorithm, the scikit-learn<sup>6</sup> implementation of the Random Forest Classification Algorithm [Bre01] is used in the application and the experiments. The default hyperparameters of the library are used. The classification experiments are conducted as multiclass problem.

For the evaluation of the compression capability of the approach, we consider the number of flows that were assigned to each region and relate their size to the number of parameters that are written to the Global Pattern Database instead. In particular we know that each simple region is represented by a single label. Hence, each simple region contains a single parameter only. Furthermore, we know the number of parameters that are stored in complex regions from Section 4.3.3, which depends on the number of unique labels in the respective region, the dimensionality of the data and the number of components of the respective GMM. As the ratio of simple and complex regions and the results from the model selection (see Algorithm 9) cannot be determined theoretically, these numbers have to be analyzed for each particular hash size and can only provide a trend and do not represent a general compression rate that is to be expected from any arbitrary dataset.

---

<sup>6</sup>Scikit-learn is a machine learning software library for the Python programming language.

## 5.3 Evaluation Results

This section presents the results from the experiments described in Section 5.2. First, the results from the baseline experiments are outlined in Section 5.3.1. Then, in Section 5.3.2 the experimental results regarding the detection performance of the presented CIDS architecture are presented. Lastly, the results in the context of overhead reduction are shown in Section 5.3.3.

### 5.3.1 Baseline Experiments

The tables regarding the classification results in the next two sections are interpreted as follows. The columns, which are grouped into skipped classes refer to the class that is removed from the respective training dataset that is indicated by the first row dimension. Four metrics are computed in a  $k$ -class problem setting for each iteration. First, the balanced accuracy score is evaluated. It shows the summarized detection performance over all  $K$  classes and is computed from the diagonal elements and the row sums of the confusion matrix  $\mathbf{C} = (c_{ij})$ . Next, the precision, recall and the balanced F-score for the class that was removed from the training dataset are computed. Thus, while the accuracy provides a way to interpret the performance regarding all classes, the latter three metrics focus on the correct detection of the class that was removed from the local training dataset. Table 5.5 shows the results from the experiments without any collaboration mechanism. As indicated by the accuracy, all classes, except for the removed class, are detected well. Note that no false positives regarding the removed class are introduced either, because the classifier did not include that class in training at all. Hence, all metrics that refer to the removed class consequently have a value of zero. In particular, by introducing data from other infrastructures in the training dataset, the classifier may not only perform better by detecting the removed class correctly, which is indicated by the recall. It may also be the case that other classes are falsely classified as the removed class, which is measured by the precision. Therefore, a low precision is interpreted as the introduction of noise that comes along with the data exchange in the CIDS. Table 5.6 shows the results of the alternative CIDS approach, where the original data is exchanged directly between members. These results are considered as a benchmark for the presented CIDS architecture in terms of the detection performance.

$$\begin{aligned}
 \text{balanced accuracy} &= \frac{1}{K} \sum_{k=1}^K \frac{c_{kk}}{\sum_{j=1}^K c_{kj}} \\
 \text{precision} &= \frac{TP}{TP + FP} \\
 \text{recall} &= \frac{TP}{TP + FN} \\
 \text{F1} &= 2 \cdot \frac{\text{precision} \cdot \text{recall}}{\text{precision} + \text{recall}}
 \end{aligned}$$

The overhead that is introduced by the direct exchange of original data between members is listed in Table 5.7. The second column shows the number of attack samples directly after the flow export. The third column shows the number of samples after removing duplicates from the collection of attack samples. The fourth column lists the number of parameters, i.e. float values, that are to be exchanged, that is the product of attack flows and their respective dimensionality (see Table 5.2).

### 5.3.2 Classification Improvement

Table 5.8 shows the results for the scenario, where members in the proposed CIDS architecture enhance local datasets with synthetic data. Values that are equal (►) or better (▲) than the results from the baseline detection scenario, where original data is exchanged (see Table 5.6), are displayed in bold font and marked with triangles respectively. Metric values from the baseline experiment that are marked with an asterisk are excluded from the comparison. Note that the asterisk marks metric values that are set to zero because of an ill-defined operation due to no predicted samples in the respective class. Table 5.9 shows the results from the scenario where, in addition to synthetic data, the classification is supported by the usage of locality sensitive hashes, i.e., patterns.

Table 5.9: The table shows the classification performance for IDSs that participate in the proposed CIDS and both utilize synthetic data and the pattern detector.

### 5.3.3 Overhead Reduction

Hash Size	Dataset	Simple		Complex			Sum	Compression
		Regions	Samples	Regions	Samples	Parameters	Parameters	Rate
16	I	596	50 083	284	306 167	38 851	39 447	0.28%
	II	649	748	343	77 009	206 765	207 414	6.84%
	III	1 170	717	341	7 041	114 569	115 739	38.25%
32	I	3 508	178 391	231	177 859	83 390	86 898	0.63%
	II	3 911	14 396	391	63 361	178 740	182 651	6.02%
	III	6 076	3 646	422	4 112	178 020	184 096	60.85%
48	I	6 351	204 021	127	152 229	66 580	72 931	0.52%
	II	7 325	52 749	262	25 008	132 562	139 887	4.61%
	III	10 569	4 426	335	3 332	181 068	191 637	63.33%

Table 5.10: The table shows the compression rates for different datasets and hash sizes.

In order to evaluate the reduction of the communication overhead, the number of attack samples in the local training datasets are put in relation to the number of parameters being exchanged in the CIDS. Table 5.10 shows the number of simple and complex regions that are created by adding the local training datasets to the pattern database. Additionally, the number of samples within all simple and complex regions are listed. As the only exchanged parameter in a simple region is the corresponding class label, the number of samples is equal to the number of exchanged parameters. In order to determine the number of parameters for the complex regions, a more detailed analysis of the exchanged GMMs and projection matrices from the PCA has to be conducted. In particular, the number of components for the dimensionality reduction via PCA, the type of covariance matrix and number of components of the GMM and the dimensionality of the input data has to be known in order to determine the number of parameters in complex regions (see Section 4.3.3). The second to last column in the table sums the number of parameters of both simple and complex region for each combination of dataset and hash size. The last column indicates the percentage of the number of parameters exchanged in the presented approach with respect to the number of parameters in the alternative CIDS (see Table 5.7). In other words, it answers the question of how small is the amount of traffic generated by the proposed architecture compared to the alternative baseline scenario.

## 5.4 Discussion

Looking first at the results of the baseline experiments, we see from Table 5.5 that those classes that were removed from the training dataset cannot be detected by the classifier. This result is not very surprising, but it illustrates again the problem of isolated IDS. The second baseline experiment (see Table 5.6) is an alternative CIDS in which attack data is exchanged directly among the participants. In addition to the data privacy problem, there is also the problem of high data volumes and the associated communication overhead. However, this experiment should first show whether it is at all possible to successfully replace missing data in local training datasets with attack data from other datasets. The results show a differentiated picture and a broad spectrum of compatibility degrees of the data among each other. For example, DDoS and bot traffic traces from different datasets are not compatible with each other at all, so that replacing them does not bring any advantage. However, it is also clear from the accuracy values that the exchange of data has at least not led to poorer detection of the other classes. On the contrary, there are certain classes for which the exchange in the CIDS has shown a large positive effect. For example, the exchange of SSH brute force traffic samples resulted in the increase of the recall for this class from 0.0 to 0.9955 and 0.9813, respectively. Additionally, almost no other classes were falsely detected as SSH brute force traffic. This means that, at least in this scenario, no noise was created by the exchange of attack traffic. Across all classes where there was a positive effect, the average increase for the precision was 0.98 and for the recall 0.45. The exchange of brute-force web traces had a positive effect in the case of infrastructure I, but not in the opposite case in infrastructure II. A potential source for this circumstance could be differences in the test data set in each case. To confirm this assumption, further experiments would be necessary, e.g. with different splittings of the training and test data sets. Table 5.7 shows two things.

First, it becomes clear that all three datasets differ significantly in the number of samples contained. On the other hand it becomes visible how significant the redundancy is in each case. Thus, the effect of deduplication is greatest for dataset III, where the number of samples is reduced by a factor of 5.6. Table 5.8 shows the results of the proposed CIDS architecture using synthetic data and without the use of pattern detection. The results not only demonstrate that the generative pattern dissemination can fill the knowledge gaps in local infrastructures, but that it provides better results than the direct exchange, although this is only valid for a hash size of 16-bit. The superiority of detection using synthetic data could be explained by improving the generalization of the model with respect to the problem. Since exactly as many samples were synthesized in the experiment as were indexed into the regions accordingly, an advantageous balancing effect over the baseline experiment is excluded. In general, the trend is that as the hash size increases, the advantages decrease. The reason for this could primarily be the amount of regions resulting from the different hash sizes. As the hash size increases, the number of regions also increases (see Table 5.10). Accordingly, the regions also contain fewer samples, since the fixed number of samples must be distributed among a larger number of regions. Consequently, the average amount of data available in a region is smaller and thus provides less input for the training of the generative model. The smaller amount of data could on average lead to a lower quality of the models. However, looking at the results of the classification with both synthetic data and the pattern detector in Table 5.9, it can be seen that an additional distinction between simple and complex regions during the classification hardly brings any advantages. On the contrary, the use of the pattern detector leads to a decrease in the detection performance compared to the results in Table 5.8. From the decreased accuracy it can be easily seen that the detection of all classes has deteriorated. In summary, this approach is on average even worse than the baseline scenario without any collaboration. The reader may have noticed that the locality sensitive hash function, which is used to create the regions, only uses different parameters for the OR-construction with respect to amplification. In other words, considering Algorithm 1, the set of different hash functions  $\{g_1, \dots, g_L\}$  in the presented approach corresponds to  $L = 1$ . Increasing  $L$  would most likely increase the recall for the corresponding classes, but would require an adaptation of the architecture and increase the memory consumption of the *PDB*. Table 5.10 shows the extent to which the data volume of the information to be exchanged can be reduced by using the *PDB*. A hash size of 16 bits achieves the best values on average. However, it is not evident that there is a general trend for the data volume to increase as the hash size increases. This is only the case for dataset III. For dataset II, the exact opposite is the case. And the volume of dataset I first increases with increasing hash size and then decreases again. The number of parameters to be exchanged does not follow any visible pattern. Note, that complex regions contain among other things GMMs, which can have in each case a different number of components, depending on the model selection. The number of components is the factor, which has the most effect on the number of the parameters of the model, since per component a mean vector and a covariance matrix must be stored. To reduce the number of parameters, a possible step would be to further reduce the maximum number of components within the model selection in the Generative Fitting Service. Nevertheless, it can be summarized that the use of the architecture with a hash size of 16-bit not only offers the best results in terms of attack detection, but also the best compression values. A reduction in data volume of up to less than 1% of the original volume can be achieved.

## Chapter 6

# Conclusion and Outlook

This thesis contributes to the field of CIDS, in particular to the topic of data dissemination. It addresses the critical aspects of this topic by presenting a collaborative data sharing architecture that aims to fill knowledge gaps in local infrastructures by providing a global view on attack data. The effectiveness of the approach was investigated by implementing the specified architecture and evaluating it in a set of comprehensive experiments. This final chapter concludes the thesis and provides a summary of all contributions in Section 6.1. In addition, an outlook on possible future work is presented in Section 6.2, which deepens specific questions or elaborates on the findings of the evaluation and proposes potential improvements.

## 6.1 Conclusion

This research aimed to design and develop a novel CIDS architecture whose data dissemination component enables the exchange of information in the context of ML-based attack detection, while respecting the critical challenges imposed on the collaboration. Based on the results of the experiments, it can be concluded that the proposed CIDS not only provides advantages compared to isolated IDSs, but is also superior to an alternative scenario in which a naive approach involving a direct exchange of original is adopted. The findings also show that the three critical requirements, namely minimal overhead, data privacy, and interoperability, have been effectively addressed. In the following, the main contributions are summarized.

The presented architecture addresses the challenges in the context of data dissemination primarily by using two mechanisms. First, information is exchanged via the exchange of generative models. To be precise, the parameters of GMMs are exchanged within the CIDS in order to create a global view of all attacks known in the CIDS which is subsequently disseminated to all members. In this context, the basic idea of exchanging parameters of ML models is not a fundamental novelty. For example, in federated learning, updates to the parameters of distributed neural networks are collected and aggregated into a global model during the execution of the backpropagation algorithm. The aggregated update values are then propagated back to all participating neural networks, so that the information from the individual training datasets is combined and made available to each participant in the federation. In contrast to that, the generative data dissemination does not exchange the parameters of the GMMs during the training phase, but instead once the training is finished. However, the biggest distinguishing feature is the way in which the exchange is managed and, in combination with the described parameter exchange, represents the actual novelty that brings significant advantages.

In fact, the compression of data by means of the transformation into generative models would not be scalable to realize without further measures. Thus, two advantages are created by partitioning the data using LSH. On the one hand, the processing of the data can be accelerated through parallelization without the risk of encountering racing conditions. In particular, workload peaks can be served dynamically in a cloud deployment. On the other hand, the continuous provision of new data is addressed by the fact that updates are only performed on individual partitions, i.e. regions. This means that when new data arrives in the CIDS, it is not necessary to reprocess the entire existing database, which is a significant advantage in general given the dynamic nature of the environment. In addition, the presented approach provides the possibility to differentiate between normal and attack data, since the training phase of the discriminative model is decoupled from the data exchange. This allows only attack data to be exchanged in the CIDS, which is then combined in the local infrastructures with the respective existing datasets, including the normal data.

# List of Abbreviations

<i>ACC</i>	accuracy score
<i>GMS</i>	generative model selection
<i>c</i> -ANNP	<i>c</i> -approximate nearest-neighbour problem
<i>cr</i> -ANNP	<i>cr</i> -approximate nearest-neighbour problem
BIC	bayesian information criterion
C&C	Command and Control
CIDS	Collaborative Intrusion Detection System
CIDSM	Collaborative Intrusion Detection System Message
DDoS	Distributed Denial of Service
DGM	Deep Generative Models
DoS	Denial of Service
DPI	Deep Packet Inspection
DR	Detection Rate
DVWA	Damn Vulnerable Web App
EM Algorithm	Expectation Maximization Algorithm
FPF	Flow Processing Format
FPR	False Postive Rate
FTP	File Transfer Protocol
GAN	Generative Adversarial Network
GMM	Gaussian Mixture Model
GRP	gaussian random projection
HIDS	Host-based Intrusion Detection System
HOIC	High Orbit Ion Cannon
HTTP	Hypertext Transfer Protocol
IDMEF	Intrusion Detection Message Exchange Format
IDS	Intrusion Detection System
IETF	Internet Enginnering Task Force
IPFIX	IP Flow Information Export
LOIC	Low Orbit Ion Cannon
LSH	locality-sensitive hashing
LVM	Latent Variable Model
MDA	Mean Decrease in Accuracy
ML	Machine Learning
MLE	Maximum Likelihood Estimation
NIDS	Network-based Intrusion Detection System
NNP	nearest-neighbour search problem
ONB	Orthonormal Basis
PCA	Principal Component Analysis

---

PDF	Portable Document Format
QoS	Quality of Service
R2L	Remote to Local
RQ	Research Question
SPoF	single point of failure
SSH	Secure Shell Protocol
TCP	Transmission Control Protocol
U2R	User to Root
UDP	User Datagram Protocol
XSS	Cross-Site Scripting

# List of Symbols

## General Mathematical Notation

$\mathbb{N}$	natural numbers
$\mathbb{R}$	real numbers
$\mathbb{R}^n$	$n$ -dimensional vector space of real numbers
$a, b, c$	scalars are lowercase
$\mathbf{x}, \mathbf{y}, \mathbf{z}$	vectors are bold lowercase
$\mathbf{A}, \mathbf{B}, \mathbf{C}$	matrices are bold uppercase
$\mathcal{A}, \mathcal{B}, \mathcal{C}$	sets
$\mathbf{x}^\top, \mathbf{A}^\top$	transpose of a vector or matrix
$\mathbf{A}^{-1}$	inverse of a matrix
$\mathbf{x}^\top \mathbf{y}$	dot product of $\mathbf{x}$ and $\mathbf{y}$
$B = (\mathbf{b}_1, \mathbf{b}_2, \mathbf{b}_3)$	(ordered) tuple
$\mathbf{B} = [\mathbf{b}_1, \mathbf{b}_2, \mathbf{b}_3]$	matrix of column vectors stacked horizontally
$\mathcal{B} = \{\mathbf{b}_1, \mathbf{b}_2, \mathbf{b}_3\}$	set of vectors
$a \in \mathcal{A}$	$a$ is element of the set $\mathcal{A}$
$a \notin \mathcal{A}$	$a$ is not element of the set $\mathcal{A}$
$\{a \in \mathcal{A} \mid \phi\}$	set containing all $a \in \mathcal{A}$ meeting condition $\phi$
$ \mathcal{A} $	cardinality of the set $\mathcal{A}$
$a \gg b$	$a$ is much greater than $b$

## Architecture Specification

$N \in \mathbb{N}$	number of data points; indexed by $n = 1, \dots, N$
$D \in \mathbb{N}$	number of dimensions; indexed by $d = 1, \dots, D$
$M \in \mathbb{N}$	number of members in the CIDS; indexed by $m = 1, \dots, M$
$\mathcal{X}$	input space

---

$\mathcal{Y}$	space of true targets, i.e., classes
$\mathcal{D}$	training dataset

# List of Tables

5.1	Exported Flows . . . . .	64
5.2	Extracted Flow Features . . . . .	65
5.3	Preprocessed Flows . . . . .	67
5.4	Attack Classes Included in the Datasets . . . . .	70
5.5	Baseline Detection Performance with Missing Class Information . . . . .	73
5.6	Baseline Detection Performance with Original Data Exchange . . . . .	73
5.7	Communication Overhead in the Baseline Experiment . . . . .	73
5.8	Detection Performance with Synthetic Data . . . . .	74
5.9	Detection Performance with Synthetic Data and Pattern Detector . . . . .	75
5.10	Parameter Number Analysis . . . . .	75

# List of Figures

2.1	A categorization of intrusions into different subtypes . . . . .	9
2.2	A taxonomy for IDS that distincts systems based on the utilized detection method or the scope in which it operates . . . . .	9
2.3	General Flow Monitoring Architecture . . . . .	11
2.4	CIDS architectures: (a) centralized, (b) hierarchical or (c) distributed layout of monitoring (M) and aggregation units (A) . . . . .	13
2.5	Components of CIDS according to functions . . . . .	14
2.6	In the $cr$ -approximate nearest-neighbour problem some point within $cr$ is accepted, if there exists a point $\mathbf{p}$ where $d(\mathbf{p}, \mathbf{q}) \leq r$ . . . . .	17
2.7	The behaviour of a conventional hashing function $h$ and a locality-sensitive hashing function $h_{\text{LSH}}$ when hashing very similar messages $\mathbf{m} \approx \mathbf{m}$ , similar messages $\mathbf{m} \sim \mathbf{m}$ and non-similar messages $\mathbf{m} \not\sim \mathbf{m}$ into the slots of a hash table $T_1$ and $T_2$ respectively. . . . .	18
2.8	The behaviour of a $(r, cr, p_1, p_2)$ -sensitive function in (a) and (b) (adapted from [LRU14, p. 100]) approaching the ideal probability gap in (c) resembling the behaviour of an exact search. . . . .	20
2.9	Illustration of a random hyperplane partitioning the space . . . . .	22
2.10	Visual Proof of claim in equation 2.9 . . . . .	23
2.11	Bivariate gaussian distributions exhibit different shapes with a changing correlation value between the random variables $x_1$ and $x_2$ : (a) negative, (b) zero and (c) positive correlation . . . . .	25
2.12	Marginals $p(x_M)$ , $p(x_N)$ and Conditional Gaussian $p(x_{M N})$ . . . . .	27
2.13	A Gaussian Mixture Model represented in plate notation . . . . .	29
2.14	Illustration of the EM algorithm for fitting a GMM with three components on a two-dimensional dataset. . . . .	32
2.15	Two synthetic datasets illustrating the difference in signal and noise . . . . .	34
4.1	Example integration of the generative pattern database into a generic NIDS deployment, seperated by data and detection level . . . . .	46
4.2	Building the global view by combining $M$ local views . . . . .	48
4.3	CIDS architecture illustrating the data and event flow between components within and across local infrastructure boundaries . . . . .	49
4.4	Nested indexing in a local pattern database. . . . .	51
4.5	Illustration of the complexity estimation algorithm with two local infrastructures. Each local label set at $PDB_{L_m}[\kappa]$ is synchronized into the global pattern database at $PDB_G[\delta]$ , where $\delta$ is constructed with $m$ . Per region, the union operation is applied on the global label sets, whereupon the complexity is derived from. . . . .	52

---

4.6	Nearest neighbours are generated by sampling each feature value from a the uniform distribution. . . . .	56
4.7	Adversary evaluation: seperate original and fake data. . . . .	58
5.1	Flow Feature Importance Analysis . . . . .	68
5.2	Implementation Details . . . . .	69

# List of Algorithms
